Introduction to Computer Programming

The List Data Structure

CSCI-UA.0002-010
Variables vs. Lists

❖ So far we have been working with variables, which can be thought of as “buckets” that hold a particular piece of data

❖ Variables can only hold one piece of data at a time. Example
  ❖ x = 5
  ❖ y = 5.0
  ❖ z = ‘hello’
  ❖ q = True

❖ However, there are times when we need to keep track of multiple pieces of data at the same time, and a single variable is limited to holding just one thing at a time
Lists

- Lists are considered a “sequence” object. Sequence objects have the ability to hold multiple pieces of data at the same time.
- We can use a single sequence variable to hold any number of values.
- In most programming languages we call these “arrays.” In Python we call these “lists.”
Lists vs. Variables
Lists in Python

- You can create a list in Python by using bracket notation. Example:

```python
my_list = [1, 2, 3]
```

- The above code will create a new list in Python that holds three integers – 1, 2 and 3 – in that order.

- Think of a list as a “book” that holds a series of sheets of paper (variables)
Lists in Python

- Lists can contain any data type that we have covered so far. Example:
  
  ```python
  my_list = ['Ada', 'John', 'Chris']
  ```

- Lists can also mix data types. Example:
  
  ```python
  my_list = ['Ada', 5.0, True, 67]
  ```

- You can print the value of a list using the `print()` function. Example:
  
  ```python
  print (my_list)
  ```
You can use the repetition operation ("*") to ask Python to repeat a list, much like how you would repeat a string. Example:

```python
my_list = [1, 2, 3] * 3
print (my_list)

>> [1, 2, 3, 1, 2, 3, 1, 2, 3]
```
List Concatenation

- You can use the concatenation operation ("+") to ask Python to combine lists, much like how you would combine strings. Example:

  ```python
  my_list = [1, 2, 3] + [99, 100, 101]
  print (my_list)
  >> [1, 2, 3, 99, 100, 101]
  ```

- Order Matters when adding one list to another.
In a book you can reference a page by its page number

In a list you can reference an element by its index number

Indexes start at the number zero.

Example:

```python
my_list = ['Ada', 'John', 'Chris']
print (my_list[0])

>> Ada
```
Invalid indexes

- You will raise an exception if you attempt to access an element outside the range of a list. For example:

```python
my_list = ['Ada', 'John', 'Chris']
print (my_list[4])  # Index doesn't exist!
```
Changing the value of an item in a list

- Lists are “mutable,” which means that they can be changed once they have been created (unlike strings) - woo hoo!

- Example:

```python
my_list = [1, 2, 3]
print (my_list)
>> [1,2,3]

my_list[0] = 99
print (my_list)
>> [99,2,3]
```
List Mechanics

- List variables are considered “references”

- This means that they “reference” or “point” to a specific region of your computer’s memory. This behavior can cause some interesting side effects. For example, the following two list variables refer to the same list in memory.

```python
mylist1 = [1,2,3]
mylist2 = mylist1

print (mylist1)
print (mylist2)

>> [1,2,3]
>> [1,2,3]
```
List Mechanics

- This means that you can change one of the lists and the change will be reflected in the other.

```python
mylist1 = [1,2,3]
mylist2 = mylist1

mylist1[0] = 999

print (mylist1)
print (mylist2)

>> [999,2,3]
>> [999,2,3]
```
Python will only create new lists when you use [] syntax to define a list for the first time.

You can take advantage of this behavior to create true copies of your list objects. For example:

```python
global mylist1 = [1,2,3]
global mylist2 = [] + mylist1

global mylist1[0] = 999

print (mylist1)
print (mylist2)
```

```
>> [999,2,3]
>> [1,2,3]
```
Creating Lists

❖ You can create an empty list with no elements using the following syntax:

mylist = []

❖ Sometimes you want to create a list that contains a certain number of "pre-set" elements. For example, to create a list with 10 elements that are all set to zero you could do the following:

mylist = [0] * 10
You can also create lists using the range() function. For example, to create a list of all even numbers between 0 and 100 you can do the following:

```python
even_numbers = list(range(0, 100, 2))
```
Iterating over a list
You can also use a for loop to iterate through a list. When you do this the target variable of your loop assumes each value of each element of the list in order. Example:

```python
my_list = [1, 2, 3]

for number in my_list:
    print(number)
```

>> 1
>> 2
>> 3
Programming Challenge: Count the A’s

❖ Given the following list:

\[
\text{grades} = [90, 100, 70, 45, 76, 84, 93, 21, 36, 99, 100]
\]

❖ Write a program that counts the # of A’s (scores between 90 and 100)

❖ Extension: Count the # of B’s, C’s, D’s and F’s
Drawbacks to using “for” loops to iterate through a List

♦ A for loop is a convenient way to sequentially iterate through a list.

♦ The target variable in a for loop assumes the value of the current item in the list as you iterate.

♦ However, the target variable isn’t very helpful if you want to change the value of an item in a list since it is just a copy of the data that exists in the list. For example:

```python
mylist = [1, 2, 3]

for n in mylist:
    n = n * 5

print (mylist)

>> [1, 2, 3]
```
In order to change a list item you need to know the index of the item you wish to change. For example:

```python
mylist = [1, 2, 3]
mylist[0] = 999
print (mylist)
```

```
[999, 2, 3]
```
Iterating over a list using index values

- There are two main techniques for iterating over a list using index values. They include:
  - Setting up a counter variable outside the list and continually updating the variable as you move to the next position in the list
  - Using the range() function to create a custom range that represents the size of your list
Using a counter variable and a for loop to iterate over a list

❖ If you set up an accumulator variable outside of your loop you can use it to keep track of where you are in a list. For example:

```python
mylist = [1, 2, 3]
counter = 0

for num in mylist:
    mylist[counter] = mylist[counter] * 2
    counter += 1

print (mylist)

>> [2, 4, 6]
```
Using the `range()` function to iterate over a list

- You can also use the `range()` function to construct a custom range that represents all of the indexes in a list. Example:

```python
mylist = [1,2,3]

for counter in range(0,len(mylist)):
    mylist[counter] = mylist[counter] * 2

print (mylist)

>> [2,4,6]
```
Given the following list of prices, write a program that modifies the list to include 7% sales tax.

```
```
Working with Lists
Creating empty lists for processing

- Since you cannot access an element outside of the range of a list it is sometimes necessary to set up a correctly sized list before you begin working with it.

- Example:

```python
# create a list of 7 zeros
daily_sales = [0] * 7
```
Programming Challenge

❖ Write a program that asks the user for daily sales figures for a full week (Sunday – Saturday)

❖ Store these values in a list and print them out at the end of the end of your program
Slicing Lists

- Sometimes you need to extract multiple items from a list.
- Python contains some built-in functions that make it easy for you to “slice” out a portion of a list. Example:

```python
list_1 = ['zero', 'one', 'two', 'three', 'four', 'five']
list_2 = list_1[1:3]

print(list_1)
print(list_2)
```

```
>> ['zero', 'one', 'two', 'three', 'four', 'five']
>> ['one', 'two']
```
Slicing Lists

❖ To slice a list you use a series of “slice indexes” to tell Python which elements you want to extract. Example:

```python
new_list = old_list[start:end]
```

❖ Python will copy out the elements from the list on the right side of the assignment operator based on the start and end indexes provided.

❖ Note that indexes work just like the range() function – you will grab items up until the end index, but you will not grab the end index itself.
Slicing Lists

- If you omit the start_index in a slice operation, Python will start at the first element of the list.
- If you omit the end_index in a slice operation, Python will go until the last element of the list.
- If you supply a third index, Python will assume you want to use a step value. This works the same as the step value you would pass to the range() function.
Given the following list:

\[
\text{my\_list} = ['a', 'b', 'c', 'd', 'e', 'f', 'g']
\]

Write a program that does the following:

- Extract the first 3 elements of the list into a new list
- Extract the characters b, c, and d into a new list
- Extract the last 4 characters into a new list

Write a program that creates a list of all #’s between 1 and 100. Then create a list of all even numbers using your first list as input.
Finding items in a list

❖ You can easily find a particular item in a list by using the “in” operator. Here’s an example:

```python
my_list = ['pie', 'cake', 'pizza']
if 'cake' in my_list:
    print("I found cake!")
else:
    print("No cake found.")
```

❖ The “in” operator lets you search for any item in a list. It will return a Boolean value that indicates whether the item exists somewhere in the list.
Given the following lists, write a program that lets the user type in a product code. If the product name exists in our inventory you should print out that it is in our inventory. Otherwise you should print out that the product is not found.

products = ['X125', 'X127', 'Z121', 'Z991']
Adding items to a list

- You have already seen a few ways in which you can add items to lists:
  - Repeat the list using the ‘*’ operator
  - Concatenate the list using the ‘+’ operator

- Another way to add items to a list is to use the ‘append’ method.

- The append method is a function that is built into the list datatype. It allows you to add items to the end of a list. Example:

```python
mylist = ['Christine', 'Jasmine', 'Renee']
mylist.append('Kate')
print(mylist)
```

```
>> ['Christine', 'Jasmine', 'Renee', 'Kate']
```
Programming Challenge

- Write a program that continually prompts a user to enter in a series of first names.
- Store these first names in a list.
- Print them out at the end of your program
You can have Python sort items in a list using the `sort()` method. Here’s an example:

```python
my_list = ['pie', 'cake', 'pizza']
my_list.append('apple')
print(my_list)

my_list.sort()
print(my_list)

>> ['pie', 'cake', 'pizza', 'apple']
>> ['apple', 'cake', 'pie', 'pizza']
```
Programming Challenge

- Take the name program you wrote earlier and update it to print out the names entered in alphabetical order.
Finding the position of an item in a list

❖ You can use the “index” method to ask Python to tell you the index of an item in a list.

❖ The “index” method takes one argument – an element to search for – and returns an integer value of where that element can be found.

❖ Caution: The index method will throw an exception if it cannot find the item in the list.

❖ Here’s an example:

```python
my_list = ['pizza', 'pie', 'cake']
if 'pie' in my_list:
    location = my_list.index('pie')
    print ('pie is at postion #', location)
else:
    print ('not found!')
```
Given that the following lists match up with one another (i.e. the product at the first position of the products list matches the price at the first position in the prices list), write a product price lookup program.

```plaintext
products = ['peanut butter', 'jelly', 'bread']
prices = [3.99, 2.99, 1.99]
```
Getting the largest and smallest values in a list

- Python has two built-in functions that let you get the highest and lowest values in a list. They are called "min" and "max" – here's an example:

```python
prices = [3.99, 2.99, 1.99]
biggest = max(prices)
smallest = min(prices)
print (smallest, 'up to', biggest)
```
Removing items from a list

- You can remove an item from a list by using the “remove” method. Here’s an example:

```
prices = [3.99, 2.99, 1.99]
prices.remove(2.99)
print (prices)
```

- Note that you will raise an exception if you try and remove something that is not in the list. Make sure to test to see if it is in the list first using the “in” operator, or use a try / except block to catch any errors you might raise.
Removing items from a list

- You can also remove an item from a list based on its index position. We can do this using the 'del' keyword, like this:

```python
prices = [3.99, 2.99, 1.99]
del prices[0] # remove whatever is at slot 0
print (prices)
```
You can use the reverse method on a list to reverse its elements.

This will not sort the list in reverse order – it will simply shuffle the elements of a list such that the first element becomes the last element, the second element becomes the second to last element, etc.
Write a weight loss program that prompts the user to enter in 7 days of weight values.

At the end of the program, print out the following:

- Weight on the first day
- Weight on the last day
- Change from the first day to the last day
- Average weight for the period
- Highest weight for the period
- Lowest weight for the period
