ABSTRACT

Writing packet-processing programs for programmable switch pipelines is challenging because of their all-or-nothing nature: a program either runs at line rate if it can fit within pipeline resources, or does not run at all. It is the compiler’s responsibility to fit programs into pipeline resources. However, switch compilers, which use rewrite rules to generate switch machine code, often reject programs because the rules fail to transform programs into a form that can be mapped to a pipeline’s limited resources—even if a mapping actually exists.

This paper presents a compiler, Chipmunk, which formulates code generation as a program synthesis problem. Chipmunk uses a program synthesis engine, SKETCH, to transform high-level programs down to switch machine code. However, naively formulating code generation as program synthesis can lead to long compile times. Hence, we develop a new domain-specific synthesis technique, slicing, which reduces compile times by 1–387x and 51x on average.

Using a switch hardware simulator, we show that Chipmunk compiles many programs that a previous rule-based compiler, Domino, rejects. Chipmunk also produces machine code with fewer pipeline stages than Domino. A Chipmunk backend for the Tofino programmable switch shows that program synthesis can produce machine code for high-speed switches.

1 INTRODUCTION

There has been a recent flurry of research on programming languages and hardware designs for high-speed programmable switch pipelines [8, 15, 23, 38–40, 73]. Today, it is possible to specify packet processing for line-rate switches at a high level of abstraction using languages like P4, making it easy for researchers, network operators, and equipment vendors to start programming switches.

However, writing optimized programs for line-rate switches is much more challenging than sample programs and tutorials [20] might suggest. A realistic switch program [22, 54, 55] must fit within highly constrained switch resource budgets to run successfully. Examples of resources include pipeline stages, arithmetic logic units (ALUs), SRAM memory for control plane rules, and containers for packet headers. To make things worse, packet-processing pipelines have an all-or-nothing characteristic: programs that can be accommodated within the switch’s resources run at the line rate of the switch pipeline; otherwise they cannot run at all. Unlike processors, there is no middle ground where complex programs can run with slightly degraded performance. This forces developers to grapple with low-level details of the hardware such as the configurations of the available ALUs, sequencing of stages, and the usage of the available stage memory (both SRAM and TCAM), to squeeze their programs into the pipeline’s resources.

The difficulty of writing optimized programs can be addressed using compilers. Today’s switch compilers [17, 69] are structured around rewrite rules [31] that operate on small program fragments at a time. These rules repeatedly transform the program into simpler forms until it can be easily mapped to machine code. However, rule-based compilers can spuriously reject many programs as they are unable to rewrite them to a form that can fit within the limited switch resources, even when there exist ways to fit those programs into the switch. §3 provides an example.

Motivated by these drawbacks of rule-based compilers and inspired by the success of program synthesis in other domains [43, 48, 62, 63, 67], a recent workshop paper [46] observed that we can leverage program synthesis, i.e., automatically generating program implementations that satisfy a specification, to produce fast packet-processing code that fits within resource limits. The workshop paper observed that synthesis can be used to transform a high-level program (e.g., in C, P4-16 [16], or Domino [69]) into low-level machine code (e.g., ALU opcodes in a switch pipeline) by treating the machine code as the program to be synthesized and the high-level program as the specification. The current paper builds on the vision in that workshop paper and makes two main research contributions in designing a switch compiler, Chipmunk.

Domain-specific synthesis techniques (§4). Synthesis is a combinatorial search problem over a space of implementations that may satisfy a specification. Hence, a synthesis-based compiler can take
2 BACKGROUND

Programming languages for packet processing. Several languages now exist for packet processing, e.g., P4-14 [27], P4-16 [16], POF [73], and Domino [69]. This paper uses Domino as the language in which the input program is specified by the programmer. Domino is well-suited to expressing packet processing with an algorithmic flavor, e.g., maintaining sketches for measurement or implementing the RCP [76] protocol. Figure 1 shows an example Domino program that samples every 11th packet going through a pipeline. Domino provides transactional semantics: operations in a Domino program execute from start to finish atomically, as though packets are being processed by the target exactly one packet at a time. This frees the programmer from having to deal with concurrency issues, delegating that to the compiler instead. The same transactional semantics are also supported by P4-16’s @atomic construct [21]. P4-16’s @atomic construct was influenced by Domino [4]; hence, we expect to also be able to support P4-16 @atomic in the frontend.

Packet-processing pipelines. A programmable switch consists of a programmable parser to parse packet headers, one or more programmable match-action ingress pipelines to manipulate headers, a packet scheduler, and one or more programmable match-action egress pipelines for additional header manipulations. We focus on the pipelines because that is where packet manipulations primarily occur. We consider a pipeline architecture for packet-processing based on RMT [39] and Banzai [1], which extends RMT with stateful computation. This architecture is now commonly known as the Protocol Independent Switch Architecture (PISA) [24] and is seen in many high-speed programmable switches [7, 8, 14, 23].

In PISA, an incoming packet first enters the parser. After parsing, the parsed packet headers are deposited in a packet header vector (PHV): a vector of containers each of which stores a single header field (e.g., IP TTL). This PHV is passed through the ingress and egress pipelines. Each pipeline stage contains multiple match-action tables that operate concurrently on PHV containers. Each match-action table identifies the rule of interest for the current packet using the match unit (e.g., SSH packets can be matched using a rule specifying TCP port 22) and modifies the packet using the action unit (e.g., adding 1 to a packet field) tied to that rule. The pipeline can maintain a small amount of action-unit-local state to perform the action, e.g., maintain a count of all SSH packets.

The PISA pipeline is assumed to be feed-forward: packets can only flow from an earlier stage to a later one, but not in reverse. This means that computations in a later stage can depend on computations in earlier ones, but not vice versa. In particular, a piece of state stored in a pipeline stage can be read, modified, and written only once by a packet as it passes through the pipeline. Switches can recirculate packets back into the pipeline to enable backward flow, but recirculation greatly degrades packet-processing throughput and we do not consider it here.

We refer to the action units in packet-processing pipelines as Arithmetic Logic Units (ALUs). In this paper, we only focus on the pipeline’s ALUs (not the match units) because the ALUs are where per-packet computation occurs—and hence the target of code generation. We further assume that the ALUs execute on all packets going through the pipeline. It is straightforward to implement use...
if (count == 10):
    count = 0
    pkt.sample = 1
else:
    count++
    pkt.sample = 0

Figure 1: Program as a packet transaction in Domino along with a 2-by-2 pipelined grid (i.e., 2 stages, 2 stateful + 2 stateless ALUs per stage) showing the PISA machine model. Input muxes are used to determine which PHV container to use as an ALU operand. Output muxes are used to determine which ALU to use to update a container.

cases where the ALUs only execute on a subset of the packets because match rules can be added to the corresponding match-action tables to support such use cases. Hence, the entire pipeline can be abstracted out as a 2D grid of ALUs (Figure 1).

ALUs must process packets at line rate. Hence, an ALU should be able to process a new packet every clock cycle (~1 ns). ALUs can be stateless, i.e., operating only on PHV containers; or stateful, i.e., operating both on ALU-local state and PHV containers. For stateless ALUs, the ALU should be able to update a new PHV container every cycle. For stateful ALUs, the entire read-modify-write operation on the state that the ALU operates on must complete within a cycle. This guarantees state consistency even if packets in consecutive cycles access the same state. Each ALU has a set of input multiplexers (muxes), one per operand. These muxes are used to determine which PHV containers are used as ALU operands. Each ALU provides certain operations (e.g., addition) and may take immediate operands. Each PHV container is fed by an output mux to determine which stateful/stateless ALU’s output updates it.

Compiling programs to pipelines. A compiler for a pipeline (e.g., Domino [69]) takes a packet-processing program, written in a high-level language, and turns it into low-level machine code representing pipeline configurations, e.g., ALU opcodes, allocation of packet fields to PHV containers, and configurations of muxes (Figure 1).

Compiling programs to pipelines is all-or-nothing: successfully compiled programs can run at the pipeline’s line rate, but a program that is rejected by the compiler can’t run at all. Programs can be rejected for two reasons. The first reason is violating resource limits: the machine code generated by the compiler might consume more resources (e.g., stages, ALUs, rule/table memory) than available. The second reason is violating computational limits: the compiler might be unable to find a way to map computations in the program to the hardware’s ALUs, even with infinite ALUs.

This places a significant responsibility on the compiler, which should ideally be able to find some machine code corresponding to the given high-level program—provided the program is within the resource and computational limits of the pipeline: the program’s computations belong to the finite space of computations possible using a single pass through the pipeline’s ALUs without recirculation. As an example of a program that exceeds these limits, if the pipeline only supports increment operations on state (but no multiply), and the program requires an exponentially weighted moving average filter over queueing delays, it is impossible to run the program using the pipeline.

3 THE CASE FOR PROGRAM SYNTHESIS

Drawbacks of rule-based compilers. Compilers for packet-processing pipelines often reject programs spuriously: a semantically-equivalent version of the same program will be accepted by the same compiler. We have observed this problem with both commercial [19] and academic compilers [6].

We illustrate the problem of spurious program rejections in the context of the Domino compiler [69] using a simple example. While this example is simplified for illustration, we have observed similar spurious program rejections with more complex examples as well. Figure 2 shows two Domino programs written to target a PISA pipeline. The two programs are semantically equivalent, i.e., given the same input packets and the same initial state variables, they will both produce the same trace of output packets and state values at run time. However, the Domino compiler exhibits a butterfly effect or a false positive compilation result: it successfully compiles the first program, but rejects the second one even though both of them have the same semantics.

To understand why, we look at the intermediate representation constructed by the Domino compiler. This representation is akin to a directed acyclic graph (DAG) of computations, but additionally groups together stateful computations that must finish atomically within one clock cycle. Figure 3 shows the DAGs for both versions of the program. The shaded nodes show stateful computations, while the unshaded nodes show stateless computations [69]. The DAGs differ in the complexity of stateful computations: the circled stateful computation of version 2 is more involved, and cannot be executed atomically by the available stateful ALU, while the stateful computations of version 1 can be. This is because the ALU considered here (the Read/Write ALU [69]) can only handle the atomic update of one state variable, but not the atomic update of two variables as required by version 2. Essentially, the compiler is running into a computational limit.

This difference in DAGs for 2 semantically equivalent programs occurs because Domino’s compiler passes are program rewrite rules that repeatedly transform the program in an attempt to find a simpler version of it (i.e., the DAG representation) that readily maps to switch ALUs. However, these rewrite rules are incomplete: they do not find a semantically-equivalent version of the DAG that can map all nodes to the available ALU type (i.e., version 1’s DAG) when given the version 2 program. In effect, the compiler’s rules do not fully explore the search space of machine code programs that could implement the high-level program.
although the specific situation in Figure 3 could be fixed by a compiler developer through the addition of another rewrite rule, similar situations will continue to emerge in the future. In fact, rule-based compilers and programs can be thought of as two sides of an arms race, with compilers getting more complex over time to incorporate more rewrite rules that simplify more complex program patterns. By contrast, as we next discuss, by exhaustively searching the space of machine code, program synthesis has the potential to provide a simpler and more future-proof compiler design.

The case for program synthesis. To address the incompleteness of rule-based compilation, we first observe that the search for machine code for a given high-level program can be thought of as a combinatorial search problem called program synthesis. In program synthesis, we are looking for a program implementation that is semantically-equivalent to a program specification: on all legal inputs, the outputs of the specification and implementation agree. In our context, implementations are drawn from the set of all machine code programs that can be implemented on a 2D ALU grid of bounded size. The specification is the high-level language program that must be compiled. The benefit of the program synthesis approach is that synthesis engines can search a family of implementations using efficient algorithms [53, 72] (see Appendix B). If at least some implementations meet the specification, the synthesis engine is far more likely to find it than a rule-based compiler. Hence, synthesis greatly reduces butterfly effects similar to Figure 2.

However, without domain-specific techniques to prune the search space of implementations, synthesis can quickly become intractable in practice. Thus our goal is to leverage synthesis for compilation because of its ability to search the machine code space, while keeping compilation times reasonable using domain-specific techniques to prune the search space. In this paper, we aim for compilation times of an hour, although most of our programs compile in a few minutes (§7.1). While an hour seems excessive, we believe that it is better than the alternative of having developers tweak programs manually, which requires low-level hardware expertise, is error prone, and may take even longer. Further, there must be some price to pay for higher quality code; other compiler techniques (e.g., link-time optimization [11]) exhibit a similar tradeoff.

4.1 Code Generation Using SKETCH

Chipmunk takes as inputs: (1) a packet transaction and (2) a specification of the pipeline’s capabilities. It produces machine code for that pipeline, which consumes a small number of resources (ALUs and pipeline stages). We first describe how we produce machine code given a fixed pipeline depth (stages) and width (ALUs per stage) (§4.1–§4.5). We then show how to use this to find code with small depth and width (§4.6).

4 CODE GENERATION AS SYNTHESIS

We briefly describe SKETCH, the program synthesis engine we use in this paper. SKETCH takes two inputs: a specification and a sketch, a partial program with holes representing unknown values in a finite range of integers. Sketches constrain the synthesis search space by only considering for synthesis those programs in which each sketch hole is filled with an integer belonging to the hole’s range. Sketches encode human insight into the shape of synthesized programs. SKETCH then fills in all holes with integers so that the completed sketch meets the specification, assuming it is possible to do so. Appendix B describes SKETCH’s internals. To build a code generator using SKETCH, we need to determine an appropriate set of holes, the sketch, and the specification.

Holes. The code generator needs to ultimately choose the right value of low-level programmable hardware knobs (Table 1), e.g., which inputs to wire to each ALU (the input muxes), what operation each performs (ALU opcodes), which PHV container is used for the outputs (output muxes), which packet field is allocated to each
We note that packet-based synthesis is a stronger requirement with finite inputs. But we can reduce trace-based synthesis to a vector, the updated state+packet vector after processing that packet possible previous state vector, even if such a state vector might be the same for the specification and the implementation. packet-based synthesis is also a solution to trace-based synthesis, and deterministic packet transactions. We then refine it to handle state and randomness.

To motivate slicing, observe that in packet-based synthesis, we require the specification and implementation to agree on the entire updated state+packet vector. Instead of requiring agreement on the entire vector, we factorize the requirement into a collection of simpler requirements or slices. Each slice is a simpler synthesis problem that synthesizes a pipelined implementation such that the implementation and the specification agree only on a single dimension of the state+packet vector (e.g., only pkt. sample or only count in Figure 1). Once we have successfully synthesized each slice, we merge together the slice implementations by stacking the resulting pipeline implementations on top of each other to form the final hardware implementation.

Slicing has two main advantages over packet-based synthesis. First, each slice can be synthesized in parallel because each slice implementation runs on an independent sub-grid of the pipeline with no overlap between the sub-grids. Second, because each slice’s implementation only satisfies a subset of the specification, i.e., one dimension instead of all dimensions of the state+packet vector, it can be synthesized using a sub-grid with smaller size than would be needed for the original specification. A smaller grid requires fewer holes to be synthesized (Table 1), reducing the synthesis time (Table 3) for any one slice relative to the original specification.

Handling state modifications. When the packet transaction modifies state, the above slicing algorithm is no longer correct. To see why, consider the specification ”count++; pkt.f = count;”. This specification sets a packet field, pkt. f, to the most recent value of a switch counter, count, which increments on every packet. This problem will be factorized into two slices: one each for pkt. f and count. In the first slice, we require an implementation that sets pkt. f to the previous count + 1. In the second slice, we require an implementation that sets count to the previous count + 1.

Note, however, the first slice does not require count itself to be updated to its correct final value. This means that the first slice can produce implementations that simply set pkt. f to the previous...
count + 1, without actually ever updating count! The result is that when a trace of multiple packets has passed through the pipeline, pkt.f will always be set to 1, i.e., the initial value of count (0) + 1. This is because count is never updated in the first slice. However, a correct implementation should set pkt.f to 1, 2, 3, . . . , over successive packets.

More generally, for any slice S, suppose there is a state variable i such that S’s packet field or state variable depends on i (e.g., pkt.f depends on count). Then we say i influences S. Then as part of the slice S, we should also require that i be updated in the implementation to match up with how the specification updates i. Otherwise, i may not be updated and S’s packet field or state variable cannot make use of the updated i for its own computation.

Hence, for each slice, we additionally assert that the specification and implementation also agree on any state variables that influence that slice’s packet field or state variable. §4.4 proves that this additional assert produces the correct behavior of all slices in the presence of state—as long as state modifications complete within a clock cycle as described in §2. In our example above, this additional assert ensures that count is also set to previous count + 1 in the first slice, in addition to pkt.f being set to previous count + 1.

Non-determinism. The use of randomness (e.g., hashing) within a vector of the function.

The cost of slicing. Slicing does not exploit opportunities to share computation between different slices. For instance, in our example, the update to count is duplicated across the two slices. Thus slicing requires additional ALUs and PHV containers for these redundant computations. In our evaluations, we find that programs do not use too many containers/ALUs in the first place (< 10) and using slicing adds at most 3 containers and ALUs per stage (Table 3). For context, RMT has about ~200 ALUs/PHV containers per stage [39]. This is a reasonable trade-off for faster compilation.

4.4 Correctness of slicing

We now prove the correctness of the slicing technique. We first introduce some notation before proving correctness.

Definition 4.1. Spec denotes the packet transaction specification for a single packet. It is a function with inputs comprising a packet vector \( \vec{p} \) and a state vector \( \vec{s} \); and with outputs comprising an updated packet vector and an updated state vector.

Individual fields in the output vector of the function can be accessed by member name or member index. For example, \( \text{Spec}(\vec{p}, \vec{s}), m \) denotes the member \( m \) of the output of the function \( \text{Spec} \) on inputs \( \vec{p} \) and \( \vec{s} \) and \( \text{Spec}(\vec{p}, \vec{s})[i] \) denotes the \( i^{th} \) member in the output vector of the function.

Definition 4.2. \( \text{Spec}^\ast \) denotes the packet transaction specification for a sequence of packets. It is a function with inputs comprising a sequence of \( n \) packets \( \{\vec{p}_i\} \), and an initial state vector \( \vec{s}_0 \); and with outputs comprising a final packet vector and a final state vector after the \( n^{th} \) packet is processed by the \( \text{Spec} \) function. It is defined inductively as follows:

\[
\text{Spec}^\ast(\{\vec{p}_1\}, \vec{s}_0) = \text{Spec}(\vec{p}_1, \vec{s}_0)
\]

\[
\text{Spec}^\ast(\{\vec{p}_n\}, \vec{s}_0) = \text{Spec}(\vec{p}_n, \text{Spec}^\ast(\{\vec{p}_{n-1}\}, \vec{s}_0))
\]

where \( \{\vec{p}_i\} \) denotes the first \( i \) packets of the input packet sequence.

Note that in the inductive step, \( \text{Spec}^\ast \) applies the \( \text{Spec} \) function to the \( n^{th} \) packet in the sequence and the output state resulting from applying \( \text{Spec}^\ast \) inductively.

Definition 4.3. \( \text{Impl} \) is a function with inputs comprising a packet vector \( \vec{p} \) and a state vector \( \vec{s} \); and with outputs comprising an updated packet vector and an updated state vector, as reflected by the functionality of the programmable switch.

Definition 4.4. \( \text{Impl}^\ast \) is a function with inputs comprising a sequence of \( n \) packets \( \{\vec{p}_i\} \) and an initial state vector \( \vec{s}_0 \), and with outputs comprising a final packet vector and a final state vector after the \( n^{th} \) packet is processed by the programmable switch. It is defined inductively as follows:

\[
\text{Impl}^\ast(\{\vec{p}_1\}, \vec{s}_0) = \text{Impl}(\vec{p}_1, \vec{s}_0)
\]

\[
\text{Impl}^\ast(\{\vec{p}_n\}, \vec{s}_0) = \text{Impl}(\vec{p}_n, \text{Impl}^\ast(\{\vec{p}_{n-1}\}, \vec{s}_0))
\]

Definition 4.5. Influence: Consider the set \( I = \{\vec{p}, \vec{s}\} \). We say that \( u \in S \) influences \( v \in S \), if there exist \( c_1 \) and \( c_2 \) such that \( \text{Spec}(\vec{p}, \vec{s})/(u), u = c_1, v \neq \text{Spec}(\vec{p}, \vec{s})/(u), u = c_2 \) or if there exists \( \text{inter} \in S \) such that \( u \) influences \( \text{inter} \) and \( \text{influence} \) influences \( v \).

Let \( I(i) \) denote a vector of indices of state variables that influence the output of the \( i^{th} \) packet field, and let \( NI(i) \) denote a vector of indices of state variables that do not influence the output of the \( i^{th} \) packet field.

Definition 4.6. Slicing-based synthesis

\[
\forall i \forall \vec{p} \forall \vec{s}, \text{Spec}^\ast(\{\vec{p}_i\}, \vec{s}_0)[i, I(i)] = \text{Impl}^\ast(\vec{p}_i, \vec{s}_0)[i, I(i)]
\]

where \( i \) represents the \( i^{th} \) packet field and \( I(i) \) is as defined above. We refer to \( \text{Impl}^\ast \) as a slicing-based implementation function for the \( i^{th} \) packet field. The \( \text{Impl} \) are “stacked” on top of each other to form \( \text{Impl}^\ast \).

Definition 4.7. Trace-based synthesis

\[
\forall i \forall \vec{p}_n \forall \vec{s}_0, \text{Spec}^\ast(\{\vec{p}_n\}, \vec{s}_0)[i, I(i)] = \text{Impl}^\ast(\vec{p}_n, \vec{s}_0)[i, I(i)]
\]

Theorem 4.8. Slicing-based synthesis \( \Rightarrow \) Trace-based synthesis.

Proof. We will prove this for any \( i \) (i.e., for all \( i^{th} \) packet fields), and by induction on \( n \), the number of packets in the sequence of packets processed by the switch.

For the base step, \( n = 1 \), we have:

\[
\text{Spec}^\ast(\{\vec{p}_1\}, \vec{s}_0)[i, I(i)] = \text{Spec}(\vec{p}_1, \vec{s}_0)[i, I(i)] \ldots (\text{def of Spec}^\ast)
\]

\[
\text{Impl}^\ast(\vec{p}_1, \vec{s}_0)[i, I(i)] = \text{Impl}(\vec{p}_1, \vec{s}_0)[i, I(i)] \ldots (\text{def of Impl}^\ast)
\]
We use SKETCH to synthesize a solution for a small input bit width and scaling up synthesis to larger input ranges. SKETCH is designed to verify it on a larger input bit width (currently all 10-bit integers). If SKETCH performs much better because it can rule out not only the hole values (hole elimination) but also all other hole assignments that could have potentially led to that counterexample.

**Constant synthesis.** One challenge for program synthesis tools is synthesizing holes with large bit ranges. In our context, these are immediate operands for ALUs, which can be up to 32 bits wide. The difficulty of synthesizing such large holes has been documented before [30, 65]. With SKETCH, we also observed a steep increase in synthesis time when using holes with bit widths exceeding 15 bits [26]. To synthesize large holes for immediate operands, we developed an algorithm based on using a dynamic pool of constants from which SKETCH picks immediate operands. Our algorithm initializes this pool to all constants that appear in the input packet transaction. In addition, we augment the pool with all numbers in a small range of integers (0–3). If Z3 verification fails, we update the pool with packet field and state variable values appearing in the counterexample produced by Z3. This algorithm is very efficient but incomplete—the main source of incompleteness in Chipmunk—because it only samples a few integer values; hence, it can fail to find a large hole when one actually exists. However, empirically, we find that it performs well because it adapts to the supplied program and learns from counterexamples.

**Canonicalization.** SKETCH needs to allocate packet fields to PHV containers and state variables to stateful ALUs, while respecting the hardware constraint that no PHV container or stateful ALU is oversubscribed. There are many feasible allocations that satisfy this constraint. However, in a symmetric grid, where the same type of ALU is tiled out over the entire grid and each ALU can use any PHV container as an operand, many of these allocations are equivalent to each other. We can use this symmetry to speed up synthesis.

In a symmetric grid, for PHV allocation, we rename packet fields so that they have canonical names f₁, f₂, ..., following [35]. Then, we allocate f₁ to container 1, f₂ to container 2, and so on. This allocation is as good as any other because in a symmetric grid all containers are equivalent in their abilities (i.e., an ALU can use any of these containers as an operand and can output to any of these containers). In other words, any allocation can be canonicalized by renaming variables.

For state variables, the situation is similar, but with one important difference. It doesn’t matter which stateful ALU within a stage a state variable is allocated to due to symmetry. However, it does matter which stage’s ALU a state variable is allocated to. This is because of dependencies within the feed-forward pipeline: an update to a state variable in a later stage can depend on the value of a state variable in an earlier stage, but the reverse is disallowed in a feed-forward pipeline. Thus state allocation exhibits symmetry within ALUs in one stage, but not across ALUs of different stages. Hence, we still use SKETCH to determine which stage a state variable should go into, but assign the state variable to a canonical stateful ALU within that stage.

### 4.5 Other Optimizations

**Scaling up synthesis to larger input ranges.** SKETCH is designed to synthesize implementations that meet the specification on a small range of inputs for each input variable (e.g., all x values between 0 and 31 in Figure 4). Scaling SKETCH to synthesize implementations that meet the specification on larger ranges of inputs (e.g., all 32-bit integers) is challenging. This is because the SAT solver within Z3 finds a counterexample, we rerun SKETCH again, using asserts to rule out the previously obtained hole values (hole elimination) or using the newly found counterexample to create an additional concrete input on which the specification and the sketch must agree (counterexample assertion). Between hole elimination and counterexample assertion, we find that counterexample assertion performs much better because it can rule out not only the hole assignment that led to the current Z3 verification counterexample, but also all other hole assignments that could have potentially led to that counterexample.

By the definition of slicing-based synthesis,

\[ \text{Spec}^\ast(\{\vec{p}_k\}, \vec{s}_0)[i, \text{I}(i)] = \text{Impl}^\ast(\{\vec{p}_k\}, \vec{s}_0)[i, \text{I}(i)] \]

Induction hypothesis: Assume that the claim holds for \( n = k \):

\[ \forall i \forall \{\vec{p}_k\} \forall \vec{s}_0, \ \text{Spec}^\ast(\{\vec{p}_k\}, \vec{s}_0)[i, \text{I}(i)] = \text{Impl}^\ast(\{\vec{p}_k\}, \vec{s}_0)[i, \text{I}(i)] \]  \hspace{1cm} (1)

Induction step: Now we prove the claim for \( n = k + 1 \)

\[ \text{Spec}^\ast(\{\vec{p}_{k+1}\}, \vec{s}_0)[i, \text{I}(i)] \]

\[ = \text{Spec}^\ast(\{\vec{p}_{k+1}\}, \vec{s}_0) \bar{\text{I}}[i, \text{I}(i)] \]  \hspace{1cm} (def of Spec^\ast)

### 4.6 Reducing Grid Size by Parallel Search

So far, we have focused on code generation for an ALU grid of a certain depth and width. To reduce resource usage, we need to find a small grid to implement each slice of the packet transaction. To
do so, we independently solve a synthesis problem for each combination of slice and grid size in parallel (Figure 5). For a packet transaction to be successfully synthesized, all its slices must be successfully synthesized at some grid size (which may be different for each slice). Thus, if a transaction can be successfully synthesized, the time to successfully synthesize that transaction is the maximum of the times to successfully synthesize each of its slices. For each slice, the time to successfully synthesize that slice is the minimum of the times to successfully synthesize that slice across all grid sizes searched. We set an upper bound on the grid size and a timeout on the synthesis time for any one of the parallel synthesis problems. For each parallel synthesis problem, we internally use SKETCH’s parallel mode [53]; thus, there are two levels of parallelism. Our parallel search strategy over grid sizes does not guarantee the smallest possible grid size for a problem, but builds on our observation that smaller grid sizes generally lead to faster synthesis times, if the slice can actually fit into the smaller grid. We have not currently implemented a full system to run synthesis problems in parallel and emulate it using sequential execution in our evaluations. However, we believe it will be straightforward to implement such a system given the embarrassingly parallel nature of our search.

5 RETARGETABLE CODE GENERATION

The techniques in the last section can generate hole-value assignments for a packet-processing program written in a high-level language, given a sketch of the pipeline. Two problems remain: (1) a sketch must be developed for the pipeline; and (2) the hole-value assignments must be mapped to a format that the hardware/backend understands.

Unfortunately, we found that developing a sketch of the pipeline manually is error-prone for several reasons (§5.1). Hence, we developed a pipeline description language, a declarative specification of a pipeline ALU’s compute capabilities and the interconnection between these ALUs (§5.1). We designed a pipeline sketch generator (§5.2) that takes specifications in this language and automatically produces a sketch of the pipeline. Thus, this pipeline description language enables retargetable code generation [10, 41]: Chipmunk can generate code for a number of different packet-processing pipelines, given a description of each pipeline.

Pipeline descriptions were also directly useful in targeting the two backends that we support, a simulator for the Banzai machine model [1] and the Tofino ASIC [23]. In particular, we were able to use declarative pipeline specifications to automatically generate executable Banzai behavioral models (§5.3), which were helpful in debugging Chipmunk itself. We also leveraged the pipeline specification language to produce a Tofino-specific code generator that

Figure 7: Workflow of Chipmunk

“lifts” the low-level hole-value assignments from Chipmunk to a surface language (i.e., P4-14) accepted by Tofino’s compiler (§5.4).

5.1 Pipeline Description Language

Writing a pipeline sketch manually is hard for three reasons.

1. Large sketches: Even for modest grid sizes (e.g., a 3-by-3 pipelined grid), the total number of hole bits and the number of lines in the sketch file often exceeds a few hundred (see Appendix A for an example sketch).

2. Different ALU capabilities on different targets: There are significant differences in the capabilities of ALUs in the different pipelines we were experimenting with: a simulator of a switch pipeline (Banzai [69]), the Tofino switch [23], and subsets of the ALU functionalities provided by either. We found that constructing a pipeline sketch manually for each of these three different cases—and each ALU within each case—was highly error-prone.

3. Diverse grid interconnects among ALUs: The specific connectivity among ALUs and PHVs differs from one pipeline to another. For example, Banzai provides all-to-all connectivity between all PHVs and ALUs: an ALU operand can come from any PHV. However, for wiring efficiency, some switching chips only provide all-to-all connectivity within clusters of PHVs and ALUs: an ALU operand can only come from a PHV in the same cluster as that ALU.

For these reasons, we developed two domain-specific languages (DSLs) to write switch pipeline specifications, one each for (1) computation (e.g., opcodes of an ALU) and (2) communication (e.g., the interconnection between these ALUs to create a pipeline through input and output muxes). Thus, the computation DSL specifies local intra-ALU features of a switch pipeline, while the communication DSL specifies global inter-ALU features of a switch pipeline. We expect these specifications to be written once at switch design time by the backend compiler developer, not repeatedly by the programmer who writes Domino programs (Figure 7).
DSL to describe ALU computation. We developed an ALU DSL (Figure 6) to specify the computational capabilities of a single switch ALU, i.e., the programmable knobs available in the ALU (Table 1). Figure 6 shows the grammar of the ALU DSL. The DSL allows a developer to specify the number of ALU operands, where each operand comes from (i.e., packet field, state, immediate operand), the ALU’s operation over its operands in the form of simplified C-like code, and what value(s) the ALU must return. Our DSL is expressive in its ability to express diverse target ALUs. It can express all the stateful and stateless instructions proposed as Banzai atoms [69], the stateless and stateful ALUs in the Tofino ASIC [23], as well as subsets of the functionality of each of these ALUs.

DSL to describe ALU interconnect. We specify the interconnections between ALUs in a grid using a grid template written in the Jinja2 template language [9]. A grid template is a skeleton of a sketch for a pipeline grid, representing the scaffolding or glue required to connect together ALUs, such as wires and muxes connecting PHVs to ALU inputs, and ALU outputs to PHVs (Figure 1). The grid template has placeholders to hold SKETCH code for ALUs (generated from the ALU DSL) and can repeat ALUs for a given width and depth.

5.2 Pipeline Sketch Generation

Chipmunk’s pipeline sketch generator takes an ALU DSL program and a grid template as input and generates a sketch (e.g., Appendix A) corresponding to the ALU, repeating ALU code as necessary to fill out the 2D grid specified in the grid template. Chipmunk then feeds the generated sketch to SKETCH, which returns a value for each hole or says that the sketch is infeasible. If it is infeasible, we return a compile error. If it is feasible, we use the hole-value assignments to program the backends (§5.3, §5.4, and §6).

5.3 Producing Behavioral Models

A declarative pipeline description language enables the automatic generation of pipeline behavioral models for the Banzai machine model from pipeline DSL specifications, akin to P4-bmv2 [28]. We designed a behavioral-model-generator, dgen [78], which takes as input a switch pipeline specification in our DSLs (§5.1) and generates Rust code that simulates the action of that pipeline on packets. The Rust code when built produces an executable version of the pipeline dsim [78], which can consume and output packets, manipulating both the packets and internal pipeline state, serving as a behavioral model for the pipeline. Thus, dsim allows us to observe the input-output behavior of machine code (e.g., ALU operands, mux settings, etc.) produced by Chipmunk.

We used dsim to fuzz-test Chipmunk using random test packets for 100+ packet transactions drawn from our programs (§7), i.e., test whether Chipmunk generates correct pipelined machine code from packet transactions. We did this in three steps. First, we created random packet vectors as test inputs. Second, we directly executed the packet transaction on these test packets to record its input-output behavior without pipelining. We performed direct execution by writing each packet transaction as a Rust function and running the Rust function repeatedly on the test packets. Third, we compare the behavior from direct execution with the behavior dsim produces on the hole-value assignments generated by Chipmunk for the same packet transaction. If the two behaviors are different, it points to a bug in Chipmunk’s code generation. Our fuzz testing has not yet revealed any bugs.

5.4 Lifting to Switch Surface Languages

Leveraging a DSL for expressing ALUs also enabled us to translate the outputs from Chipmunk’s synthesis into an input language supported by the Tofino switch compiler [19], P4-14. We did this in two steps. First, we developed a P4-14 template program in Jinja2 [9], with placeholders for P4 registers and tables, which have a one-to-one correspondence with the 2D grid of ALUs from the pipeline sketch. For instance, each stateless ALU corresponds to a P4-14 primitive action, each stateful ALU corresponds to a P4 extern [18], and each state variable corresponds to a P4-14 register.

Second, we filled in the placeholders in the P4-14 template by translating the low-level integer-valued hole-value assignments outputted by synthesis into higher level P4-14 code accepted by the Tofino compiler. In particular, we translated holes from stateless ALUs (opcodes, operands) and stateful ALUs (opcodes, operands, and choice of output PHVs) into P4-14 code by leveraging a traversal of the abstract syntax tree (AST) of the ALU expressed in our DSL. For instance, let’s say the ALU DSL file contains a function that takes three parameters: two operands (A and B) and an opcode. The hole-value assignments provide the value of the opcode, say 3, which stands for the + operation. Then, we can traverse the AST corresponding to the function and simplify the function to A+B by treating the opcode as a constant (3) and applying constant propagation on the AST.

6 EXPERIENCES WITH TOFINO

After filling in the placeholders, the P4 program is given to the Tofino compiler to generate a Tofino binary. However, this can sometimes result in an incorrect implementation due to a subtle interplay between P4’s sequential semantics and the Tofino hardware’s parallel operation. To see why, consider a “swap” packet transaction that swaps the value of two packet fields (top and bottom) without using any temporary fields. This transaction can be implemented in Tofino using a single pipeline stage with 2 ALUs (top and bottom). The top stateless ALU transfers the bottom PHV to the top PHV and the bottom stateless ALU does the reverse, using an add opcode in each ALU with 0 as one operand. Chipmunk can also generate hole-value assignments in our behavioral model for this one-stage implementation of the swap transaction.

Now, how do we realize this swap in P4? We can create two P4 tables, one for the top and bottom ALU, and use P4-14 apply statements to execute each table’s ALU on incoming packets. However, the apply statement has sequential semantics. Because each table reads a field (top/bottom) that the other writes (bottom/top), sequential semantics will force the Tofino compiler to infer a read-after-write dependency between the two tables. Hence, the Tofino compiler will place the tables in two consecutive stages, not one. This is not just wasteful in stages, it is incorrect relative to what we want: it results in both top and bottom taking the same value instead of swapping values. Here, the Tofino compiler is correctly respecting P4-14’s sequential semantics for apply statements, but the behavior is different from what Chipmunk expects from parallel
execution of the ALUs. In other words, it is hard to express the intra-stage parallelism required for operations like swap directly in P4, despite the hardware supporting it.\footnote{We note that Tofino does support a swap primitive that can be directly invoked by the programmer as an intrinsic function without writing a swap program in P4. However, the broader point illustrated by our programmer-written swap still holds: code generation requires us to express intra-stage parallelism, which is challenging.}

To address the gap in the abstraction levels between Chipmunk’s needs and P4-14, we use a compiler pragma to instruct the Tofino P4 compiler to ignore all table dependencies that it finds on its own. We instead enforce all dependencies ourselves. Chipmunk already handles dependencies because dependencies need to be respected to generate machine code that agrees with the specification. To enforce dependencies that Chipmunk finds, we use a second compiler pragma. This pragma instructs the Tofino compiler to place a table containing a stateful/stateless ALU in the same stage that the ALU belonged to in Chipmunk’s output.

Reflections. Considerable research has looked at raising the level of abstraction of languages for networking. On the other hand, when building the Tofino backend, we needed to lower the level of abstraction to enforce low-level control over the hardware using pragmas. Pragmas are effectively a mechanism to get the Tofino compiler out of the way—to perform fewer program analyses and make fewer modifications. We could have avoided pragmas and created a simpler backend if Tofino supported direct assembly programming. We hope our results make a case for switching chip vendors to support such low-level interfaces to their chips.

7 EVALUATION
Our evaluation answers the questions listed below.

(1) How does synthesis-based compilation compare to rule-based compilation? (§7.1) We investigate this using the Chipmunk and Domino compilers for the Banzai target, on the metrics of (i) ability to compile programs successfully, (ii) resource usage (i.e., pipeline stages and ALUs per stage) of successfully compiled programs, and (iii) compile time.

(2) Can synthesis effectively target a switching ASIC? (§7.2) We show experimental results using Chipmunk to target Tofino.

(3) How beneficial are slicing and the other optimizations in synthesis-based compilation? (§7.3)

Choice of baseline. For our baseline compiler, we used the Domino rule-based compiler because it can also take as input a high-level specification in transactional style, similar to Chipmunk. Domino also has a few classical compiler optimizations baked into it (e.g., common subexpression elimination, strength reduction, fusing code segments, etc.) [6]. We note that Domino also uses SKETCH for the final step of code generation after much preprocessing using classical rewrite rules [69, §4.3]. As our results show, using SKETCH so late in code generation doesn’t help significantly with compiler quality. By contrast, Chipmunk treats the entire code generation problem as a program synthesis problem, with little preprocessing.

Comparing with a commercial compiler like the Tofino compiler [19] would have been preferable to comparing with a research prototype like Domino. However, we can not directly compare with the Tofino compiler because it does not support a transactional style of programming in either of its frontend languages (P4-14 and P4-16). Instead, with the Tofino compiler, the programmer has to manually partition code into different tables and then chain together the tables to implement their desired feature—in other words, program at a lower level than the P4-16 @atomic or packet transactional style. We note, however, that we have observed the same butterfly effects that motivated our work (§2) with the Tofino compiler as well. Our results make a case for including program synthesis within commercial compilers, allowing them to support a similar transactional programming style.

Benchmarks. We collected 14 benchmarks (Table 2) from multiple sources [58, 59, 69]. These were previously written as Domino programs using the packet transactions abstraction [69]. All of these benchmarks are known to successfully compile with Domino using one of the 7 stateful atoms combined with the stateless atom proposed by Banzai [69]. We model each of these 7+1 atoms as an ALU using our ALU DSL. We verified that these benchmarks can indeed be successfully compiled with Chipmunk using the same ALU that was used for Domino.

We further create semantic-preserving rewrites of the benchmarks, which we call mutations, e.g., Figure 2. Comparing Chipmunk and Domino using mutations allows us to measure whether the two compilers can still compile mutations of an original program that was itself successfully compiled. The mutations can also be used to compare Domino and Chipmunk’s resource consumption on a larger set of programs than we started out with.

To create mutations, we added a compiler pass to the Domino compiler to modify Domino programs in semantic-preserving ways. This pass repeatedly transforms programs by randomly picking one of three transformations. The pass modifies (1) \texttt{if(x)} \texttt{B else A} into \texttt{if(!x)} \texttt{A else B} (2) \texttt{if(A and B)} into \texttt{if (B and A)}, and (3) \texttt{if(x) into if(x and 1==1)}. These mutations are simplistic and are not fully representative of the diverse ways in which developers craft programs that are semantically equivalent. Yet, even with these mutations, we demonstrate (§7.1) that Domino fails to compile many mutations, while Chipmunk successfully compiles all of them.

Experimental setup. We used a single stateless ALU type for all experiments regardless of which stateful ALU we used. This stateless ALU is modeled after the stateless atom proposed in Banzai [69]. For the stateful ALU, we used the same stateful Banzai atom for each benchmark as reported in the benchmark’s source [58, 59, 69]. Unless stated otherwise, we run Chipmunk with slicing (§4.3) and all other optimizations (§4.5) enabled. We use SKETCH’s parallel mode, which takes advantage of multi-core parallelism [53].

Recall that Chipmunk uses parallel search over different slices and grid sizes (§4.6) by running different synthesis problems on different machines. Additionally, each machine needs multiple cores for SKETCH’s parallel mode. We do not have a cluster of physical machines readily available and the cost of running unoptimized Chipmunk on EC2 is prohibitive. Instead, we used a single 32-core 64-hyperthread 256-GB RAM machine (AMD Opteron 6272) to run Chipmunk with the Banzai ALUs (§7.1 and §7.3) and used a single 28-core 56-hyperthread 64-GB RAM machine (Intel Xeon Gold 6132) to run Chipmunk with the Tofino ALUs (§7.2), and report compilation times emulating the parallel search strategy from §4.6. That is, the compile times we present in §7.1, §7.2, and §7.3 were obtained by sequential experiments, with the compile time for a given ALU grid
size being the maximum across all per-slice compile times, and the per-slice compile time being the minimum compile time across all ALU grid sizes for that slice. When we don’t use slicing, the compile time is simply the minimum compile time across all ALU grid slices. We also estimate the monetary cost of running Chipmunk with slicing on Amazon EC2.

### 7.1 Synthesis vs. Rule-Based Compilation

For each of the 14 benchmarks, we created 10 mutations using our mutating compiler pass. This gives us 140 programs to compare Domino and Chipmunk on, using the following metrics: (i) what % of the mutations of an original program can the compiler successfully compile? (we call this the \textit{compile rate}), (ii) how many pipeline stages and ALUs per stage are needed to fit the program?, (iii) how long does it take for successful compilation? We average across 10 mutations for each benchmark.

We report our results in Table 2. We find that (i) Chipmunk can compile all the mutations we produced, while Domino fails in many cases, (ii) Chipmunk’s average compilation times are longer than Domino’s, but largely fit into our time budget of ~1 hour (§3), and (iii) when both Chipmunk and Domino can both compile a mutation, Chipmunk requires fewer pipeline stages and slightly higher ALUs per stage than Domino. However, stages are far more constrained resources (e.g., 32) compared to ALUs in each stage (e.g., 224) [39].

The quality benefits of synthesis also come with a monetary cost: Chipmunk requires more compute resources than Domino (§4.6). However, this cost is reasonable. We use some typical numbers to estimate the cost of a Chipmunk compilation when implementing the strategy from §4.6 in the cloud. To estimate the degree of parallelism with slicing, we use some typical numbers from our benchmarks. Assuming 5 slices per program across both packet fields and state variables, and 10 grid sizes to be searched for each slice (i.e., up to a 3×3 grid, which is the largest grid size we search), we require around 50 VMs. We pick the m5.16xlarge spot EC2 instance [2] with 64 vCPUs and 256 GB RAM because it is closest to our local machine. With per-second billing, a one-minute minimum billing time [3], and a typical synthesis time of 5 minutes (Table 2), the compilation cost is roughly $2.66, with the fairly pessimistic assumption that all 50 VMs are occupied the entire 5 minutes. We note that the alternative of rule-based compilers will cost much more in hourly developer wages [60] due to compilation failures.

### 7.2 Compilation to Tofino Switching ASIC

After modeling the Tofino stateful and stateless ALUs using the ALU DSL (§5.1), we were able to compile and run 10 out of our 14 original benchmarks (without mutations) on Tofino. We report the resource consumption and the compilation times in Table 4. Compilation times are well within an hour for all benchmarks. The times in Tables 4 and 2 are different because (1) the ALUs are different (Banzai vs. Tofino) and (2) different machines were used.

However, we were unable to compile 4 benchmarks to Tofino. The mutations in Table 2 were theoretically guaranteed to compile to some Banzai atom because the original programs compiled to that atom; we do not have any such guarantees with Tofino as these benchmarks have not been compiled to Tofino before. In fact, for all 4 of these benchmarks, the resulting sketch file for at least one slice was infeasible up to a grid size of 2×3. Looking closer, we noticed that these 4 benchmarks need a more complicated condition for conditional state updates than supported by Tofino—a computational limit (§3). Hence, we suspect these benchmarks may not be able to compile to any grid size given our Tofino ALU model. However, we cannot yet prove that these programs cannot be compiled to even an infinite grid of a certain ALU type. Proving such “unrealizability” is an area of research in synthesis [50].

### 7.3 Benefits of Optimizations

We now compare Chipmunk’s performance with and without slicing on two metrics: pipeline resource usage and compilation time. We keep all other optimizations enabled. Table 3 shows the benefits of slicing for the Banzai backend. We observe that slicing provides a few orders of magnitude speedup on several benchmarks; this is primarily because slicing a program allows us to fit the program within a smaller grid, which translates into a smaller search space/time for SKETCH. Slicing causes a small increase in ALUs per stage because slicing does not share computations between slices. However, Chipmunk with slicing still consumes fewer stages than Domino (Table 2). Beyond performance, slicing also helped us debug the generated P4 programs on Tofino. Each slice could be tested independently on a small grid—instead of testing the whole program on a larger grid. This enabled us to localize and fix bugs in P4 code generation faster.

Even with slicing, some benchmarks (BLUE (decrease) and Stateful firewall) still incur a long synthesis time. To speed these up, we can involve the programmer in synthesis and have them set some holes in the generated sketch (e.g., ALU opcodes, output muxes) based on their insight into the program. For BLUE (decrease) and Stateful firewall, we observed speedups of 4.18× and 37.14× relative to the Chipmunk times in Table 2 by intelligently setting the value of only 3% of all the holes, hinting at the promise of an interactive approach to further reduce compile time.

We also measured the benefits of using counterexample assertion vs. hole elimination when integrating SKETCH with Z3 and the benefits of canonicalization (§4.5). Overall, with all other optimizations and slicing enabled, we observed an average 6.21× speedup with counterexample assertion vs. hole elimination and an average 11.02× speedup with canonicalization (Appendix C).

### 8 LIMITATIONS AND FUTURE WORK

We now briefly discuss Chipmunk’s main limitations along with avenues for future work. First, while Chipmunk rejects far fewer programs than Domino (Table 2), it is still incomplete and can reject feasible programs. In particular, because slicing has an additional cost PHV/ALU cost, a sliced packet transaction may no longer fit into a small grid, while the original packet transaction may have. Additionally, our constant synthesis algorithm is also incomplete. Second, even after slicing, Chipmunk’s compile times are still much longer than Domino. We believe there is still room to improve Chipmunk by exploiting dependencies between parts of the packet transaction, similar to Domino’s use of computation DAGs (Figure 3). As shown in §7.3, interactively involving the programmer can also substantially speed up synthesis-based compilation; this is another area that we plan to explore. Third, Chipmunk uses...
The ideas here are more generally applicable to FPGA [13, 51] and ASIC-based [52] SmartNIC pipelines.

We thank Armando Solar-Lezama for his detailed responses to our questions.

9 RELATED WORK

Synthesis has been applied to synthesize network updates [59, 66], routing table configurations from high-level policies [42, 74], policies from configurations [37], and control planes [75]. These efforts target network configurations and policies pertaining to access control, reachability, and isolation. In contrast, Chipmunk uses program synthesis to generate packet-processing code for programmable switches. Program slicing [77] computes a subset of program statements that can influence a variable’s value at some program location. It has been applied to debugging [77], network verification [61, 64], and query optimization [33]. Chipmunk applies slicing in the new context of machine code generation for switches, requiring considerable adaptation of the basic slicing idea (§4.3).

10 CONCLUSION

We presented Chipmunk, a program-synthesis-based compiler for switches. Chipmunk fits programs into limited switch pipeline resources—programs which might otherwise be rejected by rule-based compilers. To do so, it leverages domain-specific synthesis techniques to expedite compilation and uses a pipeline description language to target multiple backends. We hope that the techniques and results we have presented will stimulate follow-on research in designing program synthesis algorithms that compile programs faster and with fewer compute resources, and produce machine code with lower switch resource consumption. We also believe the ideas here are more generally applicable to FPGA [13, 51] and ASIC-based [52] SmartNIC pipelines.

Appendices are supporting material that has not been peer-reviewed.

A EXAMPLE OF CODE GENERATION SKETCH

This appendix presents a simplified version of the sketch generated by Chipmunk for a 2-by-2 grid and a simple spec. We use …wherever appropriate to signify that the code is similar to code presented before.

B PROGRAM SYNTHESIS USING SKETCH

We briefly describe SKETCH’s internals here; [70] has more details. SKETCH is given as inputs a specification to satisfy and a partial program (the sketch) (Figure 4). Let x be an n-bit vector representing all inputs to both the specification S and the partial program P. The task of the synthesizer is to determine values of all the holes in P such that the results of executing the partial program and the sketch on an input x, S(x) and P(x), are the same for all x. Let c be an m-bit vector representing all holes that need to be determined (or “filled in”) by SKETCH to complete the sketch. Then, the program synthesis problem solves for c in the following formula in first-order logic [72]:

\[ \exists c \in \{0,1\}^m, \forall x \in \{0,1\}^n : S(x) = P(x, c) \]  

(2)

Equation 2 is an instance of the quantified boolean formula problem (QBF) [25]. QBF is a generalization of boolean satisfiability (SAT) that allows multiple \( \forall \) and \( \exists \) quantifiers; SAT implicitly supports a single \( \forall \) or \( \exists \). While QBF solvers exist [5, 12], they are not optimized for the QBF instances found in program synthesis [70]. Hence, SKETCH uses an algorithm called counterexample-guided inductive synthesis (CEGIS) [71, 72], designed to work efficiently for the QBF instances found in program synthesis.

CEGIS (Figure 8) exploits the bounded observation hypothesis: for typical specifications, there are a small number of representative inputs that form a “perfect test suite,” i.e., if the specification and the completed sketch agree on this test suite, then they agree on all inputs. To exploit this hypothesis, CEGIS repeatedly alternates between two phases: (1) synthesizing on a small set of concrete test inputs and (2) verifying that the completed sketch matches the specification on all possible inputs. A failed verification generates a counterexample that is added to the set of concrete test inputs, and a fresh iteration of synthesis-verification follows. CEGIS terminates when either the verification phase succeeds or the synthesis phase fails, i.e., there is no way to find values for the holes that allow P and S to match on the concrete test input set.

The synthesis phase of CEGIS is represented by the following formula. Here \( x_1, x_2, \ldots, x_k \) are the current set of concrete test inputs:

\[ \exists c \in \{0,1\}^m : S(x_1) = P(x_1, c) \land \ldots \land S(x_k) = P(x_k, c) \]  

(3)

The verification phase is represented by the following formula. Here, \( c^* \) is the hole solution being verified:

\[ \forall x \in \{0,1\}^n : S(x) = P(x, c^*) \]  

(4)

Both the synthesis and verification phases of CEGIS are simpler than solving Equation 2 directly as a QBF problem. This is because each phase fixes either the test inputs (synthesis) or holes (verification) to concrete values, which turns the resulting subproblem into a SAT problem, which can be fed to a more efficient SAT (instead of QBF) solver.

C DEEP DIVE INTO CHIPMUNK OPTIMIZATIONS

We now examine the impact of our optimizations on compile time. In these experiments, we keep slicing and all other optimizations enabled, only toggling on or off one optimization.

C.1 Hole elimination vs. counterexample assertion

We considered different modes in which Z3 and SKETCH can cooperate in code generation. Our intuition was that counterexample assertion would lead to faster compile time because hole elimination only eliminates the particular hole assignment that caused that Z3 failure, while a new counterexample would eliminate all the hole assignments that could have caused that failure. Our experiments (Table 5) confirm this intuition. We set a timeout for the hole elimination to 10x the time for counterexample assertion to limit run time of our experiments; without a timeout, the benefits of counterexamples would be even more pronounced. Hence, we use counterexample assertion.

C.2 Canonical vs. synthesized allocation

We study two ways in which state variables can be allocated to stateful ALUs and packet fields can be allocated to PHV containers. In canonical allocation, as discussed in §4.5, a packet field is always
allocated to its canonical container and a state variable is always allocated to its canonical ALU after SKETCH determines its stage. In synthesized allocation, on the other hand, we disregard symmetry, and ask SKETCH to find the allocation from scratch. Hence, in synthesized allocation, SKETCH determines which container to use for a field, and which stage and which stateful ALU in that stage to use for a state variable. Table 6 shows the results. We find that canonical allocation and synthesized allocation perform similarly on benchmarks that have a short compilation time, but that canonical allocation can significantly reduce time on the longer benchmarks.
