<sup>2</sup> Courant Institute, NYU

1 **Abstract.** We address the fundamental problem of computing range  
2 functions  $\square f$  for a real function  $f: \mathbb{R} \rightarrow \mathbb{R}$ . In our previous work in IS-  
3 SAC 2021, we introduced a family of *recursive interpolation range func-*  
4 *tions* based on the Cornelius–Lohner (CL) framework of decomposing  
5  $f$  as  $f = g + R$ . The CL framework requires computing  $g(I)$  “exactly”  
6 for an interval  $I$ . There are 2 problems: this approach limits the order  
7 of convergence to 6, and exact computation is impossible to achieve in  
8 practice. We generalize the CL framework by allowing  $g(I)$  to be approx-  
9 imated by *strong range functions*  $\square g(I; \varepsilon)$ , where  $\varepsilon > 0$  is a user-specified  
10 bound on the error. This new framework allows, for the first time, the  
11 design of interval forms for  $f$  with any desired order of convergence. To  
12 achieve our strong range functions, we generalize Neumaier’s theory of  
13 constructing range functions from expressions over a Lipschitz class  $\Omega$   
14 of primitive functions. We show that the class  $\Omega$  is very extensive and  
15 includes all common hypergeometric functions. Traditional complexity  
16 analysis of range functions is based on individual evaluation on an inter-  
17 val. Such analysis cannot differentiate between our novel recursive range  
18 functions and classical Taylor-type range functions. Empirically, our re-  
19 cursive functions are superior in the “holistic” context of the root isola-  
20 tion algorithm EVAL. We now formalize this holistic approach by defin-  
21 ing the *amortized complexity* of range functions over a subdivision tree.  
22 Our theoretical model agrees remarkably well with the empirical results.  
23 Among our previous novel range functions, we identified a Lagrange-type  
24 range function  $\square_3^{L'} f$  as the overall winner. In this paper, we introduce a  
25 Hermite-type range function  $\square_4^H f$  that is even better. We further explore  
26 speeding up applications by choosing non-maximal recursion levels.

## 27 1 Introduction

28 Given a real function  $f: \mathbb{R} \rightarrow \mathbb{R}$ , the problem of tightly enclosing its range  
29  $f(I) = \{f(x) : x \in I\}$  on any interval  $I$  is a central problem of interval and  
30 certified computations [11,13]. The interval form of  $f$  may be<sup>3</sup> denoted  $\square f : \square \mathbb{R} \rightarrow \square \mathbb{R}$   
31 where  $\square \mathbb{R}$  is the set of compact intervals and  $\square f(I)$  contains the range  
32  $f(I)$ . Cornelius & Lohner [3] provided a general framework for constructing such  
33  $\square f$ . First, choose a suitable  $g: \mathbb{R} \rightarrow \mathbb{R}$  such that for any interval  $I \in \square \mathbb{R}$ , we can

<sup>3</sup> Definitions of our terminology are collected in Section 1.3.

34 compute  $g(I)$  exactly. Then  $f(I) = g(I) + R_g(I)$  where  $R_g(x) := f(x) - g(x)$ .  
 35 The standard measure for the accuracy of approximate functions like  $\square f$  is their  
 36 order of convergence. Suppose  $R_g$  has an interval form  $\square R_g$  with convergence  
 37 order  $n \geq 1$ . Then

$$\square_g f(I) := g(I) + \square R_g(I) \tag{1}$$

38 is an interval form for  $f$  with order of convergence  $n$ . This is an immediate  
 39 consequence of the following theorem.

**Theorem A [3, Theorem 4].**

$$d_H(f(I), \square_g f(I)) \leq w(\square R_g(I)).$$

40 where  $d_H$  is the Hausdorff distance on intervals and  $w(I)$  is the width of inter-  
 41 val  $I$ .

42 Prior to [3], interval forms with convergence order larger than 2 were unknown.  
 43 Cornelius & Lohner showed that there exists  $g$  such that  $\square R_g$  has convergence  
 44 order up to 6.

45 *Example 1.* Let  $g(x)$  be the Taylor expansion of  $f(x)$  at  $x = m$  up to order  
 46  $n \geq 1$  and  $R_g(x) = \frac{f^{(n+1)}(\xi_x)}{(n+1)!} (x - m)^{n+1}$  for some  $\xi_x$  between  $x$  and  $m$ . Then  
 47 the following is a range function for  $R_g(I)$ :

$$\square R_g(I) := \frac{|\square f^{(n+1)}(I)|}{(n+1)!} \left( \frac{w(I)}{2} \right)^{n+1}, \tag{2}$$

48 where  $I = [a, b]$ ,  $m = (a + b)/2$ , and  $w(I) = b - a$ . Assuming that  $I \subseteq I_0$  for  
 49 some bounded  $I_0$ , we have  $\frac{|\square f^{(n+1)}(I)|}{(n+1)!} = O(1)$ . Then (2) implies that  $\square R_g(I)$   
 50 has convergence order  $n + 1$ . If  $n \leq 3$ , then  $g(I)$  can be computed “exactly”  
 51 as described in [9, Appendix]. This proves the existence of range functions of  
 52 order 4.

### 53 1.1 Why we must extend the CL framework

54 Unfortunately, there is an issue with the CL framework: *we cannot compute*  
 55 *the “exact range  $g(I)$ ” in any standard implementation models.* Standard im-  
 56 plementation models include (i) the IEEE arithmetic used in the majority of  
 57 implementations, (ii) the Standard Model of Numerical Analysis [8,17], or (iii)  
 58 bigNumber packages such as GMP [7], MPFR [6], and MPFI [14]. In practice,  
 59 “real numbers” are represented by dyadic numbers, i.e., rational numbers of the  
 60 form  $m2^n$  where  $m, n \in \mathbb{Z}$ . So, rational numbers like  $1/3$  cannot be exactly rep-  
 61 resented. Even if we allow arbitrary rational numbers, irrational numbers like  $\sqrt{2}$   
 62 are not exact. See, for example, [20] for an extended discussion of exact compu-  
 63 tation. In computer algebra systems, the largest set of real numbers which can be  
 64 computed exactly are the algebraic numbers, but we do not include them under  
 65 “standard implementation models” because of inherent performance issues.

66 In [9], we used the term “exact computation of  $g(I)$ ” in a sense which is  
 67 commonly understood by interval and numerical analysts, including Cornelius  
 68 & Lohner. But first let us address the non-interval case: the “exact computation  
 69 of  $g(x)$ ”. The common understanding amounts to:

*$g(x)$  can be computed exactly if  $g(x)$  has a closed-form  
 expression  $E(x)$  over a set  $\Omega$  of primitive operations.* (3)

70 There is no universal consensus on the set  $\Omega$  but typically all real constants,  
 71 four rational operations ( $\pm$ ,  $\times$ ,  $\div$ ), and  $\sqrt{\cdot}$  are included. E.g., Neumaier [11, p. 6]  
 72 allows these additional operations in  $\Omega$ :

$$|\cdot|, \text{ sqr}, \exp, \ln, \sin, \cos, \arctan,$$

73 where<sup>4</sup> *sqr* denotes squaring. Next, how does the understanding (3) extend to  
 74 the exact computation of  $g(I)$ ? Cornelius & Lohner stated a sufficient condition  
 75 that is well-known in interval analysis [3, Theorem 1]:

*$g(I)$  can be computed exactly if there is an expression  $E(x)$   
 for  $g(x)$  in which the variable  $x$  occurs at most once.* (4)

76 It is implicitly assumed in (4) that, given an expression  $E(x)$  for  $g(x)$ , we can  
 77 compute  $g(I)$  by evaluating the interval expression  $E(I)$ , assuming all the prim-  
 78 itive operators in  $E(x)$  have exact interval forms. But this theorem has very  
 79 limited application, and cannot even compute the exact range of a quadratic  
 80 polynomial  $g(x) = ax^2 + bx + c$  with  $ab \neq 0$ .

81 *Example 2.* To overcome the limitations of (4) in the case of a quadratic poly-  
 82 nomial  $g(x) = ax^2 + bx + c$ , we can proceed as follows: first compute  $x^* = -b/2a$ ,  
 83 the root of  $g'(x) = 2ax + b$ . If  $I = [\underline{x}, \bar{x}]$ , then

$$g(I) = [\min(S), \max(S)],$$

where

$$S := \begin{cases} \{g(\underline{x}), g(\bar{x})\} & \text{if } x^* \notin I, \\ \{g(x^*), g(\underline{x}), g(\bar{x})\} & \text{else.} \end{cases}$$

84 We call this the “endpoints algorithm”, since we directly compute the end-  
 85 points of  $g(I)$ . The details when  $g$  is a cubic polynomial are derived and imple-  
 86 mented in our previous paper [9, Appendix]. How far can we extend this idea?  
 87 Under the common understanding (3), we need two other ingredients:

- 88 (E1) The function  $g(x)$  must be exactly computable.
- 89 (E2) The roots of  $g'(x)$  must be exactly computable.

90 Note that (E1) is relatively easy to fulfill. For instance,  $g(x)$  can be any poly-  
 91 nomial. However, (E2) limits  $g$  to polynomials of degree at most 5, since the  
 92 roots of  $g'$  are guaranteed to have closed form expressions when  $g'$  has degree  
 93 at most 4. Cornelius & Lohner appear to have this endpoint algorithm in mind  
 94 when they stated in [3, p. 340, Remark 2] that their framework may reach up to  
 95 order 6 convergence, namely one more than the degree of  $g$ .

<sup>4</sup> The appearance of *sqr* may be curious, but that is because he will later define interval forms of the operations in  $\Omega$ .

96 **1.2 Overview**

97 In Section 2, we present our generalized CL framework for achieving range func-  
 98 tions with any order of convergence. In Section 3, we provide details for a new  
 99 family of *recursive range operators*<sup>5</sup>  $\{\square_{4,\ell}^H : \ell = 0, 1, \dots\}$  with quartic conver-  
 100 gence order and recursion level  $\ell \geq 0$ , based on Hermite interpolation. In  
 101 Section 4, we present our “holistic” framework for evaluating the complexity of  
 102 range functions. The idea is to amortize the cost over an entire computation  
 103 tree. Experimental results are in Section 5. They show that in the context of  
 104 the EVAL algorithm,  $\square_4^H$  is superior to our previous favorite  $\square_3^{L'}$ . The theoretical  
 105 model of Section 4 is also confirmed by these experiments. Another set of exper-  
 106 iments explore the possible speed improvements by non-maximal convergence  
 107 levels. We conclude in Section 6.

108 **1.3 Terminology and notation**

109 This section reviews and fixes some terminology. Let  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  be a real  
 110 function for some  $n \geq 0$ . The *arity* of  $f$  is  $n$ . We identify 0-arity functions with  
 111 real constants. In this paper, we do not assume that real functions are total  
 112 functions. If  $f$  is undefined at  $\mathbf{x} \in \mathbb{R}^n$ , we write  $f(\mathbf{x}) \uparrow$ ; otherwise  $f(\mathbf{x}) \downarrow$ . If any  
 113 component of  $\mathbf{x}$  is undefined, we also have  $f(\mathbf{x}) \uparrow$ . Define the *proper domain* of  
 114  $f$  as  $\text{dom}(f) := \{\mathbf{x} \in \mathbb{R}^m : f(\mathbf{x}) \downarrow\}$ . If  $S \subseteq \mathbb{R}^m$ , then  $f(S) \uparrow$  if  $f$  is undefined at  
 115 some  $\mathbf{x} \in S$ ; else  $f(S) := \{f(\mathbf{x}) : \mathbf{x} \in S\}$ . Define the *magnitude* of  $S \subseteq \mathbb{R}$  as  
 116  $|S| := \max\{|x| : x \in S\}$ . Note that we use bold font like  $\mathbf{x}$  to indicate vector  
 117 variables.

118 The set of compact boxes in  $\mathbb{R}^n$  is denoted  $\square\mathbb{R}^n$ ; if  $n = 1$ , we simply write  
 119  $\square\mathbb{R}$ . The Hausdorff distance on boxes  $B, B' \in \square\mathbb{R}^n$  is denoted  $d_H(B, B')$ . For  
 120  $n = 1$ , it is often denoted  $q(I, J)$  in the interval literature. A *box form* of  
 121  $f$  is any function  $F : \square\mathbb{R}^n \rightarrow \square\mathbb{R}$ , satisfying two properties: (1) *conservative*:  
 122  $f(B) \subseteq F(B)$  for all  $B \in \square\mathbb{R}^n$ . (2) *convergent*: for any sequence  $(B_i)_{i=0}^\infty$  of boxes  
 123 converging to a point,  $\lim_{i \rightarrow \infty} F(B_i) = f(\lim_{i \rightarrow \infty} B_i)$ . In general, we indicate  
 124 box forms by a prefix meta-symbol “ $\square$ ”. Thus, instead of  $F$ , we write “ $\square f$ ” for  
 125 any box form of  $f$ . We annotate  $\square$  with subscripts and/or superscripts to indicate  
 126 specific box forms. E.g.,  $\square_i f$  or  $\square^L f$  or  $\square_i^L f$  are all box forms for  $f$ . In this paper,  
 127 we mostly focus on  $n = 1$ . A *subdivision tree* is a finite tree  $T$  whose nodes are  
 128 intervals satisfying this property: if interval  $[a, b]$  is a non-leaf node of  $T$ , then it  
 129 has two children represented by the intervals  $[a, m]$  and  $[m, b]$ . If  $I_0$  is the root  
 130 of  $T$ , we call the set  $\mathcal{D} = \mathcal{D}(T)$  of leaves of  $T$  a *subdivision* of  $I_0$ .

131 For Turing computability of our box functions, we replace real intervals  $\square\mathbb{R}$   
 132 by *dyadic intervals*  $\square\mathbb{D}$ , i.e., intervals whose endpoints are dyadic numbers which  
 133 are elements of  $\mathbb{D} = \{m2^{-n} : m, n \in \mathbb{Z}\}$ . A real function  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  is said to  
 134 be *computable* if its restriction to dyadic inputs will produce dyadic outputs,

<sup>5</sup> Each  $\square_{4,\ell}^H$  is an operator that transforms any sufficiently smooth function  $f : \mathbb{R} \rightarrow \mathbb{R}$   
 into the range function  $\square_{4,\ell}^H f$  for  $f$ .

135 and this restriction is Turing computable. This notion extends to box functions,  
 136  $\square f : \square \mathbb{R}^n \rightarrow \square \mathbb{R}$ .

137 Let  $\mathbf{u} = (u_0, \dots, u_m)$  denote a sequence of  $m + 1$  distinct points, where  
 138 the  $u_i$ 's are called *nodes*. Let  $\boldsymbol{\mu} = (\mu_0, \dots, \mu_m)$ , where each  $\mu_i \geq 1$  is called  
 139 a *multiplicity*. The *Hermite interpolant* of  $f$  at  $\mathbf{u}, \boldsymbol{\mu}$  is a polynomial  $h_f(x) =$   
 140  $h_f(x; \mathbf{u}, \boldsymbol{\mu})$  such that  $h_f^{(j)}(u_i) = f^{(j)}(u_i)$  for all  $i = 0, \dots, m$  and  $j = 0, \dots, \mu_i -$   
 141  $1$ . The interpolant  $h_f(x)$  is unique and has degree less than  $d = \sum_{i=0}^m \mu_i$ . If  
 142  $m = 0$ , then  $h_f(x)$  is the Taylor interpolant; if  $\mu_i = 1$  for all  $i$ , then  $h_f(x)$  is the  
 143 Lagrange interpolant.

## 144 2 Generalized CL Framework

145 In this section, we develop an approach to computing range functions of arbitrary  
 146 convergence order. To avoid the exact range computation, we replace  $g(I)$  in (1)  
 147 by a range function  $\square g(I)$  for  $g$ :

$$\square f(I) := \square g(I) + \square R_g(I) \quad (5)$$

148 We now generalize Theorem A as follows.

**Theorem B.** *With  $\square f(I)$  defined as in (5), we have*

$$d_H(f(I), \square f(I)) \leq d_H(g(I), \square g(I)) + w(\square R_g(I)).$$

*Proof.* Consider the endpoints of the intervals  $f(I), g(I)$  and  $\square R_g(I)$  as given by

$$f(I) = [f(\underline{x}), f(\bar{x})], \quad g(I) = [g(\underline{y}), g(\bar{y})], \quad \square R_g(I) = [a, b]$$

for some  $\underline{x}, \bar{x}, \underline{y}, \bar{y} \in I$  and  $a, b$ . We can also write

$$\square g(I) = [g(\underline{y}), g(\bar{y})] + [\underline{\varepsilon}, \bar{\varepsilon}]$$

149 for some  $\underline{\varepsilon} \leq 0 \leq \bar{\varepsilon}$ . Thus we have

$$\begin{aligned} d_H(g(I), \square g(I)) &= \max\{-\underline{\varepsilon}, \bar{\varepsilon}\}, \\ \square f(I) &= [g(\underline{y}), g(\bar{y})] + [\underline{\varepsilon}, \bar{\varepsilon}] + [a, b]. \end{aligned} \quad (6)$$

We write the inclusion  $f(I) \subseteq \square f(I)$  in terms of endpoints:

$$[f(\underline{x}), f(\bar{x})] \subseteq [g(\underline{y}), g(\bar{y})] + [\underline{\varepsilon}, \bar{\varepsilon}] + [a, b].$$

150 Hence

$$d_H(f(I), \square f(I)) = \max\{f(\underline{x}) - (g(\underline{y}) + \underline{\varepsilon} + a), (g(\bar{y}) + \bar{\varepsilon} + b) - f(\bar{x})\}$$

151 Since  $w(\square R_g(I)) = b - a$  and in view of (6), our theorem follows from

$$f(\underline{x}) - (g(\underline{y}) + \underline{\varepsilon} + a) \leq -\underline{\varepsilon} + (b - a), \quad (7)$$

$$(g(\bar{y}) + \bar{\varepsilon} + b) - f(\bar{x}) \leq \bar{\varepsilon} + (b - a). \quad (8)$$

152 To show (7), we have, since  $f(\underline{x}) \leq f(\underline{y})$ ,

$$\begin{aligned}
 f(\underline{x}) - (g(\underline{y}) + \underline{\varepsilon} + a) &\leq f(\underline{y}) - (g(\underline{y}) + \underline{\varepsilon} + a) \\
 &= (g(\underline{y}) + R_g(\underline{y})) - (g(\underline{y}) + \underline{\varepsilon} + a) \\
 &= R_g(\underline{y}) - \underline{\varepsilon} - a \\
 &\leq -\underline{\varepsilon} + (b - a).
 \end{aligned}$$

153 The proof for (8) is similar.

## 154 2.1 Achieving any order of convergence

155 To apply Theorem B, we introduce *precision-bounded range functions* for  $g(x)$   
 156 denoted  $\square g(I; \varepsilon)$ , where  $\varepsilon > 0$  is an extra “precision” parameter. The output  
 157 interval is an *outer  $\varepsilon$ -approximation* in the sense that  $g(I) \subseteq \square g(I; \varepsilon)$  and

$$d_H(g(I), \square g(I; \varepsilon)) \leq \varepsilon.$$

158 We also call  $\square g(I; \varepsilon)$  a *strong box function*, since it implies box forms in the  
 159 original sense: E.g., a box form of  $g$  may be constructed as follows:

$$\square g(I) := \square g(I, w(I)). \quad (9)$$

160 The box form in (9) has the pleasing property that  $w(I)$  is an implicit precision  
 161 parameter.

162 Returning to the CL Framework, suppose  $f = g + R_g$  where  $g$  has a strong  
 163 range function  $\square g(I; \varepsilon)$ . We now define the following box form of  $f$ :

$$\square_{\text{pb}} f(I) := \square g(I; \varepsilon) + \square R_g(I), \quad (10)$$

164 where  $\varepsilon = |\square R_g(I)|$ . The subscript in  $\square_{\text{pb}}$  refers to “precision-bound”. To com-  
 165 pute  $\square_{\text{pb}} f(I)$ , we first compute  $J_R \leftarrow \square R_g(I)$ , then compute  $J_g \leftarrow \square g(I, |J_R|)$ ,  
 166 and finally return  $J_g + J_R$ .

167 **Corollary 1.** *The box form  $\square_{\text{pb}} f(I)$  of (10) has the same convergence order as*  
 168  *$\square R_g(I)$ .*

169 For any  $n \geq 1$ , if  $g(x)$  is a Hermite interpolant of  $f$  of degree  $n$ , then  $\square R_g(I)$   
 170 has convergence order  $n + 1$  (cf. Example 1.1). We have thus achieved arbitrary  
 171 convergence order.

172 *Remark 1.* Theorem B is also needed to justify the usual implementations of  
 173 “exact  $g(I)$ ” under the hypothesis (3) of the CL framework. Given an expres-  
 174 sion  $E(x)$  for  $g(x)$ , it suffices to evaluate it with error at most  $|\square R_g(I)|$ . This  
 175 can be automatically accomplished in the Core Library using the technique of  
 176 “precision-driven evaluation” [21, §2].

177 **2.2 Strong box functions**

178 Corollary 1 shows that the “exact computation of  $g(I)$ ” hypothesis of the CL  
 179 framework can be replaced by strong box functions of  $g$ . We now address the  
 180 construction of such functions. We proceed in three stages:

181 *A. Lipschitz Expressions.* Our starting point is the theory of evaluations of  
 182 expressions over a class  $\Omega$  of Lipschitz functions, following [11]. Let  $\Omega$  denote  
 183 a set of continuous real functions that includes  $\mathbb{R}$  as constant functions as well  
 184 as the rational operations. Elements of  $\Omega$  are called *primitive functions*. Let  
 185  $\text{Expr}(\Omega)$  denote the set of expressions over  $\Omega \cup X$  where  $X = \{X_1, X_2, \dots\}$  is  
 186 a countable set of variables. An expression  $E \in \text{Expr}(\Omega)$  is an ordered DAG  
 187 (directed acyclic graph) whose nodes with outdegree  $m \geq 0$  are labeled by  $m$ -  
 188 ary functions of  $\Omega$ , with variables in  $X$  viewed as 0-ary. For simplicity, assume  
 189  $E$  has a unique root (in-degree 0). Any node of  $E$  induces a subexpression. If  $E$   
 190 involves only the variables in  $\mathbf{X} = (X_1, \dots, X_n)$ , we may write  $E(\mathbf{X})$  for  $E$ . We  
 191 can evaluate  $E$  at  $\mathbf{a} \in \mathbb{R}^n$  by substituting  $\mathbf{X} \leftarrow \mathbf{a}$  and evaluating the functions  
 192 at each node in a bottom-up fashion. The value at the root is  $E(\mathbf{a})$  and may  
 193 be undefined. If  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  is a function, we call  $E$  an *expression for  $f$*  if the  
 194 symmetric difference  $\text{dom}(E) \Delta \text{dom}(f)$  is a finite set. E.g., if  $f(x) = \sum_{i=0}^{n-1} x^i$ ,  
 195 then  $E(X_1) = \frac{X_1^n - 1}{X_1 - 1}$  is an expression for  $f$  since  $f(a) = E(a)$  for  $a \neq 1$ , but  
 196  $f(1) = n$  and  $E(1) \uparrow$ . Similarly, we can define the *interval value*  $E(B)$  at the  
 197 box  $B = (I_1, \dots, I_n) \in \square \mathbb{R}^n$ . If each  $f$  in  $E$  is replaced by a box form  $\square f$ , we  
 198 obtain a *box expression*  $\square E(\mathbf{X})$ .

199 Following [11, pp. 33, 74], we say that  $E(\mathbf{X})$  is *Lipschitz* at  $B \in \square \mathbb{R}^n$  if the  
 200 following properties hold inductively:

- 201 – (Base case) The root of  $E$  is labeled by a variable  $X_i$  or a constant function.  
 202 This always holds.
- 203 – (Induction) Let  $E = f(E_1, \dots, E_m)$ , where each  $E_j$  is a subexpression of  $E$ .  
 204 Inductively, each  $E_i$  is Lipschitz at  $B$ . Moreover,  $f(E_1(B), \dots, E_m(B))$  is  
 205 defined and  $f$  is Lipschitz<sup>6</sup> in a neighborhood  $U$  of  $(E_1(B), \dots, E_m(B)) \subseteq$   
 206  $\square \mathbb{R}^m$ .

**Theorem C [11, p. 34].** *If  $E(\mathbf{x})$  is a Lipschitz expression on  $B_0 \in \square \mathbb{R}^n$ , then there is a vector  $\ell = (\ell_1, \dots, \ell_n)$  of positive constants such that for all  $B, B' \subseteq B_0$ ,*

$$d_H(E(B), E(B')) \leq \ell * d_H(B, B'),$$

207 *where  $d_H(B, B') = (d_H(I_1, I'_1), \dots, d_H(I_n, I'_n))$  and  $*$  is the dot product.*

208 Theorem C can be extended to the box form  $\square E(\mathbf{X})$ , and thus  $\square E(B)$  is an  
 209 enclosure of  $E(B)$ . To achieve strong box functions, we will next strengthen  
 210 Theorem C to compute explicit Lipschitz constants.

<sup>6</sup> The concept of a function  $f$  (not expression) being Lipschitz on a set  $U$  is standard: it means that there exists a vector  $\ell = (\ell_1, \dots, \ell_m)$  of positive constants, such that for all  $\mathbf{x}, \mathbf{y} \in U \subseteq \mathbb{R}^m$ ,  $|f(\mathbf{x}) - f(\mathbf{y})| \leq \ell * |\mathbf{x} - \mathbf{y}|$  where  $*$  is the dot product and  $|\mathbf{x} - \mathbf{y}| = (|x_1 - y_1|, \dots, |x_m - y_m|)$ . Call  $\ell$  a *Lipschitz constant vector* for  $U$ .

211 *B. Lipschitz<sup>+</sup> Expressions.* For systematic development, it is best to begin with  
 212 an *abstract model* of computation that assumes  $f(B)$  and  $\partial_i f(B)$  are computable.  
 213 Eventually, we replace these by  $\sqcap f(B)$  and  $\sqcap \partial_i f(B)$ , and finally we make them  
 214 Turing computable by using dyadic approximations to reals. This follows the  
 215 “AIE methodology” of [19]. Because of our limited space and scope, we focus on  
 216 the abstract model.

217 Call  $\Omega$  a *Lipschitz<sup>+</sup> class* if each  $f \in \Omega$  is a Lipschitz<sup>+</sup> function in this sense  
 218 that  $f$  has continuous partial derivatives at its proper domain  $\text{dom}(f)$  and both  $f$   
 219 and its gradient  $\nabla f = (\partial_1 f, \dots, \partial_m f)$  are locally Lipschitz. Given an expression  
 220  $E(\mathbf{X})$  over  $\Omega$ , we can define  $\nabla E := (\partial_1 E, \dots, \partial_n E)$ , where each  $\partial_i E(\mathbf{X})$  is an  
 221 expression, defined inductively as

$$\partial_i E(\mathbf{X}) = \begin{cases} 0 & \text{if } E = \text{const}, \\ \delta(i = j) & \text{if } E = X_j, \\ \sum_{j=1}^m (\partial_j f)(E_1, \dots, E_m) \cdot \partial_i E_j & \text{if } E = f(E_1, \dots, E_m). \end{cases}$$

222 Here,  $\delta(i = j) \in \{0, 1\}$  is Kronecker’s delta function that is 1 if and only if  $i = j$ .

223 *C. Strong Box Evaluation* Let  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  be a Lipschitz<sup>+</sup> function. Suppose it  
 224 has a *strong approximation function*  $\tilde{f}$ , i.e.,

$$\tilde{f} : \mathbb{R}^n \times \mathbb{R}_{>0} \rightarrow \mathbb{R}, \quad (11)$$

225 such that  $|\tilde{f}(\mathbf{a}; \varepsilon) - f(\mathbf{a})| \leq \varepsilon$ . We show that  $f$  has a strong box function. Define  
 226  $\Delta(f, B) := \frac{1}{2} \sum_{i=1}^n |\partial_i f(B)| \cdot w_i(B)$ . Then, for all  $\mathbf{a} \in B$ , we have

$$|f(\mathbf{a}) - f(\mathbf{m}(B))| \leq \Delta(f, B). \quad (12)$$

227 by the Mean Value Theorem.

228 **Lemma 1.** *Suppose  $\Delta(f, B) \leq \varepsilon/4$ . If*

$$J := [\tilde{f}(\mathbf{m}(B); \varepsilon/4) \pm \frac{1}{2}\varepsilon], \quad (13)$$

229 *then  $f(B) \subseteq J$  and  $d_H(J, f(B)) < \varepsilon$ .*

230 Motivated by Lemma 1, we say that a subdivision  $\mathcal{D}$  of  $B_0$  is  $\varepsilon$ -*fine* if  $\Delta(f, B) \leq$   
 231  $\varepsilon/4$  for each  $B \in \mathcal{D}$ . Given an  $\varepsilon$ -fine subdivision  $\mathcal{D}$  of  $B_0$ , let  $J(\mathcal{D}) := \bigcup_{B \in \mathcal{D}} J(B)$ ,  
 232 where  $J(B)$  is defined in (13).

233 **Corollary 2.** *If  $\mathcal{D}$  is an  $\varepsilon$ -fine subdivision of  $B_0$ , then  $f(B_0) \subseteq J(\mathcal{D})$  and*  
 234  *$d_H(f(B_0), J(\mathcal{D})) < \varepsilon$ .*

235 Algorithm 1 shows how to compute an  $\varepsilon$ -fine subdivision of any given  $B_0$ .

236 Note that the value of  $\Delta(f, B)$  is reduced by a factor less than or equal  
 237 to  $(1 - \frac{1}{2^n})$  with each bisection, and therefore the subdivision depth is at most  
 238  $\ln(\varepsilon/\Delta(f, B_0))/\ln(1 - \frac{1}{2^n})$ . This bound is probably overly pessimistic (e.g.,  $|J_i| =$   
 239  $|\partial_i f(B)|$  is also shrinking with depth). We plan to do an amortized bound of this  
 240 algorithm. In any case, we are now able to state the key result.

---

**Algorithm 1** Fine Subdivision Algorithm

---

**Input:**  $(f, B_0, \varepsilon)$ **Output:** An  $\varepsilon$ -fine subdivision  $\mathcal{D}$  of  $B_0$ .

```
1: Let  $Q, \mathcal{D}$  be queues of boxes, initialized as  $\mathcal{D} \leftarrow \emptyset$  and  $Q \leftarrow \{B_0\}$ .
2: while  $Q \neq \emptyset$  do
3:    $B \leftarrow Q.\text{pop}()$ 
4:    $(J_1, \dots, J_n) \leftarrow \nabla f(B)$ 
5:    $\Delta(f, B) \leftarrow \sum_{i=1}^n |J_i| \cdot w_i(B)$ 
6:   if  $\Delta(f, B) \leq \varepsilon/4$  then
7:      $\mathcal{D}.\text{push}(B)$ 
8:   else
9:      $i^* \leftarrow \operatorname{argmax}_{i=1, \dots, n} |J_i| \cdot w_i(B)$ 
10:     $Q.\text{push}(\text{bisect}(B, i^*))$  ▷ Bisect dimension  $i^*$ 
11: Output  $\mathcal{D}$ 
```

---

241 **Theorem D.** Let  $\Omega$  be a Lipschitz<sup>+</sup> class, where each  $f \in \Omega$  has a strong  
242 approximation function as in (11). If  $E(\mathbf{X})$  is an expression that is Lipschitz<sup>+</sup>  
243 over  $B \in \square\mathbb{R}^n$ , then the strong interval function  $E(B; \varepsilon)$  is abstractly computable.

244 *Proof (Proof sketch).* Use induction on the structure of  $E(\mathbf{X})$ . The base case is  
245 trivial. If  $E(\mathbf{X}) = f(E_1, \dots, E_m)$ , then, by induction,  $\tilde{I}_i = E_i(B; \varepsilon_i)$  is abstractly  
246 computable ( $i = 1, \dots, m$ ). Lemma 1 can be generalized to allow the evaluation  
247 of  $f(\tilde{B}; \varepsilon)$ , where  $\tilde{B} = (\tilde{I}_1, \dots, \tilde{I}_m)$ .

248 Which functions satisfy the requirements of Theorem D? One of the most  
249 extensive classes with strong approximation algorithms is the class of hyper-  
250 geometric functions; Johansson [10] describes a state-of-the-art library for such  
251 functions. In [4,5], we focused on the real hypergeometric functions and provide a  
252 uniform algorithm with complexity analysis for rational input parameters. Note  
253 that Theorem D also needs strong box functions which were not treated in [5,10];  
254 such extensions could be achieved because hypergeometric functions are closed  
255 under differentiation. A complete account of the preceding theory must replace  
256 the abstract computational model by box functions  $\square f$ , finally giving dyadic  
257 approximations  $\tilde{\square} f$  following the AIE methodology in [19].

### 258 3 A Practical Range Function of Order 4

259 In this section, we consider a new recursive range function based on Hermite  
260 interpolation which will surpass the performance of  $\square_3^L f$  [9]. Let  $h_0$  be the  
261 Hermite interpolant of  $f$  based on the values and first derivatives at the endpoints  
262 of the interval  $I = [a, b]$ , that is,  $h_0$  is the unique cubic polynomial with

$$h_0(a) = f(a), \quad h_0'(a) = f'(a), \quad h_0(b) = f(b), \quad h_0'(b) = f'(b).$$

263 With  $m = (a + b)/2$  denoting the midpoint of  $I$ , it is not hard to show that  $h_0$   
264 can be expressed in centered form as

$$h_0(x) = c_{0,0} + c_{0,1}(x - m) + c_{0,2}(x - m)^2 + c_{0,3}(x - m)^3$$

265 with coefficients

$$\begin{aligned} c_{0,0} &= \frac{f(a) + f(b)}{2} - \frac{f'(b) - f'(a)}{4}r, & c_{0,1} &= 3\frac{f(b) - f(a)}{4r} - \frac{f'(a) + f'(b)}{4}, \\ c_{0,2} &= \frac{f'(b) - f'(a)}{4r}, & c_{0,3} &= \frac{f'(a) + f'(b)}{4r^2} - \frac{f(b) - f(a)}{4r^3}, \end{aligned}$$

266 where  $r = (b - a)/2$  is the radius of  $I$ . Since the remainder  $R_{h_0} = f - h_0$  can be  
267 written as

$$R_{h_0}(x) = \frac{\omega(x)}{4!}f^{(4)}(\xi_x), \quad \omega(x) = (x - a)^2(x - b)^2,$$

268 for some  $\xi_x \in I$ , we can upper bound the magnitude of  $R_{h_0}(I)$  as

$$|R_{h_0}(I)| \leq \Omega|f^{(4)}(I)|, \quad \Omega = \frac{|\omega(I)|}{4!} = \frac{r^4}{24}.$$

269 To further upper bound  $|f^{(4)}(I)|$ , following [9, Sec. 3], we consider the cubic  
270 Hermite interpolants  $h_j$  of  $f^{(4j)}$  for  $j = 1, 2, \dots, \ell$ :

$$h_j(x) = c_{j,0} + c_{j,1}(x - m) + c_{j,2}(x - m)^2 + c_{j,3}(x - m)^3$$

271 with coefficients

$$\begin{aligned} c_{j,0} &= \frac{f^{(4j)}(a) + f^{(4j)}(b)}{2} - \frac{f^{(4j+1)}(b) - f^{(4j+1)}(a)}{4}r, \\ c_{j,1} &= 3\frac{f^{(4j)}(b) - f^{(4j)}(a)}{4r} - \frac{f^{(4j+1)}(a) + f^{(4j+1)}(b)}{4}, \\ c_{j,2} &= \frac{f^{(4j+1)}(b) - f^{(4j+1)}(a)}{4r}, \\ c_{j,3} &= \frac{f^{(4j+1)}(a) + f^{(4j+1)}(b)}{4r^2} - \frac{f^{(4j)}(b) - f^{(4j)}(a)}{4r^3}. \end{aligned}$$

272 Denoting the remainder by  $R_{h_j} = f^{(4j)} - h_j$  and using the same arguments as  
273 above, we have

$$|f^{(4j)}(I)| \leq |h_j(I)| + |R_{h_j}(I)| \leq |h_j(I)| + \Omega|f^{(4j+4)}(I)|. \quad (14)$$

274 By repeated application of (14), we get

$$\begin{aligned} |f^{(4)}| &\leq |h_1(I)| + \Omega|f^{(8)}(I)| \\ &\leq |h_1(I)| + \Omega(|h_2(I)| + \Omega|f^{(12)}(I)|) \leq \dots \\ &\leq \sum_{j=1}^{\ell} |h_j(I)|\Omega^{j-1} + \Omega^{\ell}|\square f^{(4\ell+4)}(I)|, \end{aligned} \quad (15)$$

275 resulting in the recursive remainder bound

$$|R_{h_0}(I)| \leq S_{\ell}, \quad S_{\ell} := \sum_{j=1}^{\ell} |h_j(I)|\Omega^j + \Omega^{\ell+1}|\square f^{(4\ell+4)}(I)|.$$

276 Overall, we get the *recursive Hermite form* of order 4 and *recursion level*  $\ell \geq 0$ ,

$$\square_{4,\ell}^H f(I) = h_0(I) + [-1, 1]S_\ell,$$

277 which depends on the  $4\ell + 4$  values

$$f^{(4j)}(a), f^{(4j+1)}(a), f^{(4j)}(b), f^{(4j+1)}(b), \quad (j = 0, \dots, \ell). \quad (16)$$

278 If  $f$  is analytic and  $r$  is sufficiently small, or if  $f$  is a polynomial, then  $S_\infty$  is a  
 279 convergent series and we define  $\square_4^H f(I) := \square_{4,\infty}^H f(I)$  as the *maximal recursive*  
 280 Hermite form. Clearly, if  $f$  is a polynomial of degree at most  $d - 1$ , then  $\square_4^H f =$   
 281  $\square_{4,\ell}^H f$  for  $\ell = \lceil d/4 \rceil - 1$ .

282 To avoid the rather expensive evaluation of the exact ranges  $h_j(I)$ ,  $j =$   
 283  $1, \dots, \ell$ , we can use the classical Taylor form for approximating them, resulting  
 284 in the cheaper but slightly less tight range function

$$\square_{4,\ell}^{H'} f(I) = h_0(I) + [-1, 1]S'_\ell,$$

285 where

$$S'_\ell = \sum_{j=1}^{\ell} (|c_{j,0}| + r|c_{j,1}| + r^2|c_{j,2}| + r^3|c_{j,3}|) \Omega^j + \Omega^{\ell+1} |\square f^{(4\ell+4)}(I)|.$$

286 In case we also have to estimate the range of  $f'$ , we can compute the  $2\ell + 2$   
 287 additional values

$$f^{(4j+2)}(a), f^{(4j+2)}(b), \quad j = 0, \dots, \ell \quad (17)$$

288 and apply  $\square_{4,\ell}^H$  to  $f'$ . But we prefer to avoid (17) by re-using the data used for  
 289 computing  $\square_{4,\ell}^H f(I)$  in the following way. A result by Shadrin [15] asserts that  
 290 the error between the first derivative of  $f$  and the first derivative of the Lagrange  
 291 polynomial  $L(x)$  that interpolates  $f$  at the 4 nodes  $x_0, \dots, x_3 \in I$  satisfies

$$|f'(x) - L'(x)| \leq \frac{|\omega'_L(I)|}{4!} |f^{(4)}(I)|, \quad x \in I,$$

292 for  $\omega_L(x) = \prod_{i=0}^3 (x - x_i)$ . As noted by Waldron [18, Addendum], this bound is  
 293 continuous in the  $x_i$ , and so we can consider the limit as  $x_0$  and  $x_1$  approach  $a$   
 294 and  $x_2$  and  $x_3$  approach  $b$  to get the corresponding bound for the error between  
 295  $f'$  and the first derivative of the Hermite interpolant  $h_0$ ,

$$|f'(x) - h'_0(x)| \leq \frac{|\omega'(I)|}{4!} |f^{(4)}(I)|, \quad x \in I.$$

296 Since a straightforward calculation gives  $\omega'(I) = \frac{8}{9}\sqrt{3}r^3[-1, 1]$ , we conclude  
 297 by (15) that

$$|R'_{h_0}(I)| \leq \frac{8\sqrt{3}}{9} \frac{r^3}{4!} |f^{(4)}(I)| \leq \frac{8\sqrt{3}}{9} \frac{r^3}{4!} \frac{S_\ell}{\Omega} = \frac{8\sqrt{3}}{9r} S_\ell,$$

298 resulting in the recursive Hermite forms

$$\square_{3,\ell}^H f'(I) = h'_0(I) + \frac{8\sqrt{3}}{9r}[-1, 1]S_\ell \quad \text{and} \quad \square_{3,\ell}^{H'} f'(I) = h'_0(I) + \frac{8\sqrt{3}}{9r}[-1, 1]S'_\ell,$$

299 which have only cubic convergence, but depend on the same data as  $\square_{4,\ell}^H f(I)$   
 300 and  $\square_{4,\ell}^{H'} f(I)$ .

## 301 4 Holistic Complexity Analysis of Range Functions

302 By the “holistic complexity analysis” of  $\square f(I)$ , we mean to analyze its cost over  
 303 a subdivision tree, not just its cost at a single isolated interval. The cost for a  
 304 node of the subdivision tree might be shared with its ancestors, descendants,  
 305 or siblings, leading to cheaper cost per node. Although we have the EVAL algo-  
 306 rithm [9, Section 1.2] in mind, there are many applications where the algorithms  
 307 produce similar subdivision trees, even in higher dimensions.

### 308 4.1 Amortized complexity of $\square_3^{L'} f$

309 We first focus on the range function denoted  $\square_3^{L'} f$  in [9]. This was our “function  
 310 of choice” among the 8 range functions studied in [9, Table 1]. Empirically, we  
 311 saw that  $\square_3^{L'}$  has at least a factor of 3 speedup over  $\square_2^T$ . Note that  $\square_2^T$  was the  
 312 state-of-the-art range function before our recursive forms; see the last column of  
 313 the Tables 3 and 4 in [9]. We now show theoretically that the speedup is also 3 if  
 314 we only consider evaluation complexity. The data actually suggest an asymptotic  
 315 speedup of at least 3.5 – this may be explained by the fact that  $\square_3^{L'}$  has order 3  
 316 convergence compared to order 2 for  $\square_2^T$ . We now seek a theoretical account of  
 317 the observed speedup<sup>7</sup>.

In the following, let  $d \geq 2$ . Given any  $f$  and interval  $[a, b]$ , our general goal  
 is to construct a range function  $\square f([a, b])$  based on  $d$  derivatives of  $f$  at points  
 in  $[a, b]$ . In the case of  $\square_3^{L'} f([a, b])$ , we need these evaluations of  $f$  and its higher  
 derivatives:

$$f^{(3j)}(a), \quad f^{(3j)}(m), \quad f^{(3j)}(b), \quad j = 0, \dots, \lceil d/3 \rceil - 1,$$

318 where  $m = (a + b)/2$ . That is a total of  $3 \lceil d/3 \rceil$  derivative values. For simplicity,  
 319 assume  $d$  is divisible by 3. Then the *cost* for computing  $\square_3^{L'} f([a, b])$  is  $3 \lceil d/3 \rceil = d$ .  
 320 Note that the cost to compute  $\square_2^T f(I)$ , the maximal Taylor form of order 2, is  
 321 also  $d$ . So there is no difference between these two costs over isolated intervals.  
 322 But in a “holistic context”, we see a distinct advantage of  $\square_3^{L'}$  over  $\square_2^T$ : the

---

<sup>7</sup> Note that in our EVAL application, we must simultaneously evaluate  $\square_3^{L'} f(I)$  as well  
 as its derivative  $\square_2^{L'} f'(I)$ . But it turns out that we can bound the range of  $f'$  for no  
 additional evaluation cost.

323 evaluation of  $\square_3^{L'} f(I)$  can reuse the derivative values already computed at the  
 324 parent or sibling of  $I$ ; no similar reuse is available to  $\square_2^T$ .

325 Given a subdivision tree  $T$ , our goal is to bound the *cost*  $C_3^L(T)$  of  $\square_3^{L'} f$   
 326 on  $T$ , i.e., the total number of derivative values needed to compute  $\square_3^{L'} f(I)$  for  
 327 all  $I \in T$ . We will write  $C_3^L(n)$  instead of  $C_3^L(T)$  when  $T$  has  $n$  leaves. This is  
 328 because it is  $n$  rather than the actual<sup>8</sup> shape of  $T$  that is determinative for the  
 329 complexity. We have the following recurrence:

$$C_3^L(n) = \begin{cases} d & \text{if } n = 1, \\ C_3^L(n_L) + C_3^L(n_R) - \frac{d}{3} & \text{if } n \geq 2, \end{cases} \quad (18)$$

330 where the left and right subtrees of the root have  $n_L$  and  $n_R$  leaves, respectively.  
 331 Thus  $n = n_L + n_R$ . Let the intervals  $I, I_L, I_R$  denote the root and its left and right  
 332 children. The formula for  $n \geq 2$  in (18) comes from summing three costs: (1) the  
 333 cost  $d$  at the root  $I$ ; (2) the cost  $C_3^L(n_L)$  but subtracting  $2d/3$  for derivatives  
 334 shared with  $I$ ; (3) the cost  $C_3^L(n_R) - 2d/3$  attributed to the right subtree.

335 **Theorem 1.** (*Amortized Complexity of  $\square_3^{L'}$* )

$$C_3^L(n) = (2n + 1) \cdot \frac{d}{3}. \quad (19)$$

336 Thus the cost per node is  $\sim d/3$  asymptotically.

337 *Proof.* The solution (19) is easily shown by induction using the recurrence (18).  
 338 To obtain the cost per node, we recall that a full binary tree with  $n$  leaves has  
 339  $2n - 1$  nodes. So the average cost per node is  $\frac{2n+1}{2n-1} \cdot \frac{d}{3} \sim d/3$ .

340 This factor of 3 improvement over  $\square_2^T$  is close to our empirical data in [9].

## 341 4.2 Amortized complexity of $\square_4^H f$

342 We do a similar holistic complexity analysis for the recursive range function  
 343  $\square_{4,\ell}^H f(I)$  from Section 3 for any given  $f$  and  $\ell \geq 0$ . According to (16), our re-  
 344 cursive scheme requires the evaluation of  $4(\ell + 1)$  derivatives of  $f$  at the two  
 345 ends of  $I$ . Let  $d = 4(\ell + 1)$ , so that computing  $\square_{4,\ell}^H f(I)$  costs  $d$  derivative eval-  
 346 uations. For holistic analysis, let  $C_4^H(n)$  denote the cost of computing  $\square_{4,\ell}^H f(I)$   
 347 on a subdivision tree with  $n$  leaves. We then have the recurrence

$$C_4^H(n) = \begin{cases} d & \text{if } n = 1, \\ C_4^H(n_L) + C_4^H(n_R) - \frac{d}{2} & \text{if } n \geq 2, \end{cases} \quad (20)$$

348 where  $n_L + n_R = n$ . The justification of (20) is similar to (18), with the slight  
 349 difference that the midpoint of an interval  $J$  is not evaluated and hence not  
 350 shared with the children of  $J$ .

<sup>8</sup> If  $d$  is not divisible by 3, we can ensure a total cost of  $d$  evaluations per interval of  
 the tree but the tree shape will dictate how to distribute these evaluations on the  
 $m + 1$  nodes.

351 **Theorem 2.** (*Amortized Complexity of  $\square_4^H$* )

$$C_4^H(n) = (n + 1) \cdot \frac{d}{2}. \quad (21)$$

352 *Thus the cost per node is  $\sim d/4$  asymptotically.*

353 *Proof.* The solution (21) follows from (20) by induction on  $n$ . Since a full binary  
354 tree with  $n$  leaves has  $2n - 1$  nodes, the average cost per node is  $\frac{n+1}{2n-1} \frac{d}{2} \sim d/4$ .

355 Thus we expect a 4-fold speedup of  $\square_4^H$  when compared to the state-of-art  
356  $\square_2^T$ . Or a 4/3-fold or 33% speedup when compared to  $\square_3^{L'}$ . This agrees with our  
357 empirical data below.

### 358 4.3 Amortized complexity for Hermite schemes

359 We now generalize the analysis above. Recall from Section 1.3 that  $h_f(x) =$   
360  $h_f(x; \mathbf{u}, \boldsymbol{\mu})$  is the Hermite interpolant of  $f$  with node sequence  $\mathbf{u} = (u_0, \dots, u_m)$   
361 and multiplicity  $\boldsymbol{\mu} = (\mu_0, \dots, \mu_m)$ . We fix the function  $f : \mathbb{R} \rightarrow \mathbb{R}$ . Assume  
362  $m \geq 1$  and the nodes are equally spaced over the interval  $I = [u_0, u_m]$ , and all  
363  $\mu_i$  are equal to  $h \geq 1$ . Then we can simply write  $h(x; I)$  for the interpolant on  
364 interval  $I$ . Note that  $h(x; I)$  has degree less than  $d := (m + 1)h$ .

365 Our cost model for computing  $\square f(I)$  is the number of evaluations of deriva-  
366 tives of  $f$  at the nodes of  $I$ . Based on our recursive scheme, this cost is exactly  
367  $d = (m + 1)h$  since  $I$  has  $m + 1$  nodes. To amortize this cost over the entire sub-  
368 division tree  $T$ , define  $N_m(T)$  to be the number of distinct nodes among all the  
369 intervals of  $T$ . In other words, if intervals  $I$  and  $J$  share a node  $u$ , then we do not  
370 double count  $u$ . This can happen only if  $I$  and  $J$  have an ancestor-descendant  
371 relationship or are siblings. Let  $T_n$  denote a tree with  $n$  leaves. It turns out that  
372  $N_m(T_n)$  is a function of  $n$ , independent of the shape of  $T_n$ . So we simply write  
373  $N_m(n)$  for  $N_m(T_n)$ . Therefore<sup>9</sup> the *cost of evaluating the tree  $T_n$*  is

$$C_d^h(n) := h \cdot N_m(n), \quad \text{where } d = (m + 1)h.$$

374 Since  $T_n$  has  $2n - 1$  intervals, we define the *amortized cost* of a recursive Hermite  
375 range function as

$$\bar{C}_d^h = \lim_{n \rightarrow \infty} \frac{C_d^h(n)}{2n - 1}.$$

**Theorem 3.**

$$\begin{aligned} N_m(n) &= mn + 1, \\ C_d^h(n) &= h(mn + 1), \\ \bar{C}_d^h &= \frac{1}{2}hm = \frac{1}{2}(d - h). \end{aligned}$$

<sup>9</sup> The notation “ $C_d^h(n)$ ” does not fully reproduce the previous notations of  $C_3^L(n)$  and  $C_4^H(n)$  (which were chosen to be consistent with  $\square_3^{L'}$  and  $\square_4^H$ ). Also,  $d$  is implicit in the previous notations.

376 *Proof.* We claim that  $N_m(n)$  satisfies the recurrence

$$N_m(n) = \begin{cases} m + 1 & \text{if } n = 1, \\ N_m(n_L) + N_m(n_R) - 1 & \text{if } 1 < n = n_L + n_R. \end{cases} \quad (22)$$

377 The base case is clear, so consider the inductive case: the left and right subtrees  
 378 of  $T_n$  are  $T_{n_L}$  and  $T_{n_R}$ , where  $n = n_L + n_R$ . Then nodes at the root of  $T_n$  are  
 379 already in the nodes at the roots of  $T_{n_L}$  and  $T_{n_R}$ . Moreover, the roots of  $T_{n_L}$  and  
 380  $T_{n_R}$  share exactly one node. This justifies (22). The solution  $N_m(n) = mn + 1$  is  
 381 immediate. The amortized cost is  $\lim_{n \rightarrow \infty} C_d^h(n)/(2n - 1)$  since the tree  $T_n$  has  
 382  $2n - 1$  intervals.

383 *Remark 2.* Observe that the amortized complexity  $\overline{C}_d^h = \frac{d-h}{2}$  is strictly less than  
 384  $d$ , the non-amortized cost. For any given  $d$ , we want  $h$  as large as possible, but  $h$  is  
 385 constrained to divide  $d$ . Hence for  $d = 4$ , we choose  $h = 2$ . We can also generalize  
 386 to allow multiplicities  $\mu$  to vary over nodes: e.g., for  $d = 5$ ,  $\mu = (2, 1, 2)$ .

387 *Remark 3.* The analysis of  $C_3^L(n)$  and  $C_4^H(n)$  appears to depend on whether  $m$   
 388 is odd or even. Surprisingly, we avoided such considerations in the above proof.

## 389 5 Experimental Results

390 To provide a holistic application for evaluating range functions, we use EVAL,  
 391 a simple root isolation algorithm. Despite its simplicity, EVAL produces near-  
 392 optimal subdivision trees [1,16] when we use  $\square_2^T f$  for real functions with simple  
 393 roots; see [9, Sections 1.2, 1.3] for its description and history. We now imple-  
 394 mented a version of EVAL in *C++* for range functions that may use any recur-  
 395 sion level (unlike [9] which focused on maximal levels). We measured the size  
 396 of the EVAL subdivision tree as well as the average running time of EVAL with  
 397 floating point and rational arithmetic on various classes of polynomials. These  
 398 polynomials have varying root structures: dense with all roots real (Chebyshev  
 399  $T_n$ , Hermite  $H_n$ , and Wilkinson's  $W_n$ ), dense with only 2 real roots (Mignotte  
 400 cluster  $M_{2k+1}$ ), and sparse without real roots ( $S_n$ ). Depending on the fam-  
 401 ily of polynomials, we provide different centered intervals  $I_0 = [-r(I_0), r(I_0)]$   
 402 for EVAL to search in, but always such that *all* real roots are contained in  
 403  $I_0$ . Our experimental platform is a Windows 10 laptop with a 1.8 GHz Intel  
 404 Core i7-8550U processor and 16 GB of RAM. We use two kinds of computer  
 405 arithmetic in our testing: 1024-bit floating point arithmetic and multi-precision  
 406 rational arithmetic. In rational arithmetic,  $\sqrt{3}$  is replaced by the slightly larger  
 407  $17320508075688773 \times 10^{-16}$ . Our implementation, including data and Makefile  
 408 experiments, may be downloaded from the Core Library webpage [2].

409 We tested eleven versions of EVAL that differ by the range functions used for  
 410 approximating the ranges of  $f$  and  $f'$ ; see Tables 1-3. The first three,  $E_2^T$ ,  $E_3^{L'}$ ,  
 411  $E_4^{L'}$ , are the state-of-the-art performers from [9], followed by three non-maximal  
 412 variants of  $E_3^{L'}$ , namely  $E_{3,\ell}^{L'}$  for  $\ell \in \{10, 15, 20\}$ . The next two,  $E_4^H$  and  $E_4^{H'}$ ,

413 are based on the maximal recursive Hermite forms  $\square_4^H f$  and  $\square_3^H f'$  and their  
414 cheaper variants  $\square_4^{H'} f$  and  $\square_3^{H'} f'$ , respectively, and the last three derive from  
415 the non-maximal variants of the latter, again for recursion levels  $\ell \in \{10, 15, 20\}$ .

416 Table 1 reports the sizes of the EVAL subdivision trees, which serve as a measure  
417 of the tightness of the underlying range functions. In each row, the smallest  
418 tree size is underlined. As expected, the methods based on range functions with  
419 quartic convergence order outperform the others, and in general the tree size de-  
420 creases as the recursion level increases, except for sparse polynomials. It requires  
421 future research to investigate the latter. We further observe that the differences  
422 between the tree sizes for  $E_4^{L'}$  and  $E_4^{H'}$  are small, indicating that the tightness  
423 of a range function is determined mainly by the convergence order, but much  
424 less by the type of local interpolant (Lagrange or Hermite). However, as already  
425 pointed out in [9], a smaller tree size does not necessarily correspond to a faster  
426 running time. In fact,  $E_3^{L'}$  was found to usually be almost as fast as  $E_4^{L'}$ , even  
427 though the subdivision trees of  $E_3^{L'}$  are consistently bigger than those of  $E_4^{L'}$ .

428 In Tables 2 and 3 we report the running times for our eleven EVAL versions  
429 and the different families of polynomials. Times are given in seconds and aver-  
430 aged over at least four runs (and many more for small degree polynomials). The  
431 last three columns in both tables report the speedup ratios  $\sigma(\cdot)$  of  $E_4^{H'}$ ,  $E_{4,15}^{H'}$ ,  
432 and  $E_{3,15}^{L'}$  with respect to  $E_3^{L'}$ , which was identified as the overall winner in [9].

433 In Figure 1, we provide a direct comparison of the EVAL version based on our  
434 new range function  $E_4^{H'}$  with the previous leader  $E_3^{L'}$ : for the test polynomials  
435 in our suite, the new function is faster for polynomials of degree greater than  
436 25, with the speedup approaching and even exceeding the theoretical value of  
437 1.33 of Section 4.2. In terms of tree size they are similar (differing by less than  
438 5%, Table 1). Hence,  $E_4^{H'}$  emerges as the new winner among the practical range  
439 functions from our collection.

440 **5.1 Non-maximal recursion levels**

441 High order of convergence is important for applications such as numerical dif-  
442 ferential equations. But a sole focus on convergence order may be misleading as  
443 noted in [9]: for any convergence order  $k \geq 1$ , a subsidiary measure may be crit-  
444 ical in practice. For Taylor forms, this is the *refinement level*  $n \geq k$  and for our  
445 recursive range functions, it is the *recursion level*  $\ell \geq 0$ . Note that Ratschek [12]  
446 has a notion called “order  $n \geq 1$ ” for box forms on rational functions that  
447 superficially resembles our level concept. When restricted to polynomials, it

**Fig. 1.** Speedup  $\sigma$  of  $E_4^{H'}$  with respect to  $E_3^{L'}$  for different families of polynomials and varying degree: raw (left) and smoothed with moving average over five points (right).

**Fig. 2.** Speedup  $\sigma(\ell)$  of  $E_{3,\ell}^{L'}$  (left) and  $E_{4,\ell}^{H'}$  (right) against their maximal level counterparts with respect to  $\ell$  for polynomials of degree 125 (top) and 250 (bottom) from different families.

448 diverges from our notion. In other words, we propose to use<sup>10</sup> the pair  $(k, \ell)$

<sup>10</sup> This is a notational shift from our previous paper. We previously indexed the recursion level by  $n \geq 1$ . Thus, level  $\ell$  in this paper corresponds to  $n - 1$  in the old notation.

449 of convergence measures in evaluating our range functions. In [9] we focused  
 450 on maximal levels (for polynomials) after showing that the  $\tilde{\square}_2^T$  (the minimal  
 451 level Taylor form of order 2) is practically worthless for the EVAL algorithm.  
 452 We now experimentally explore the use of non-maximal levels.

453 Figure 2 plots the (potential) *level speedup factor*  $\sigma(\ell)$  against level  $\ell \geq 0$ .  
 454 More precisely, consider the time for EVAL to isolate the roots of a polynomial  
 455  $f$  in some interval  $I_0$ . Let  $\square_{k,\ell}f$  be a family of range functions of order  $k$ , but  
 456 varying levels  $\ell \geq 0$ . If  $E_{k,\ell}$  (resp.,  $E_k$ ) is the running time of EVAL using  
 457  $\square_{k,\ell}f$  (resp.,  $\square_{k,\infty}f$ ), then  $\sigma(\ell) := E_k/E_{k,\ell}$ . Of course, it is only a true speedup  
 458 if  $\sigma(\ell) > 1$ . These plots support our intuition in [9] that minimal levels are  
 459 rarely useful (except at low degrees). Most strikingly, the graph of  $\sigma(\ell)$  shows a  
 460 characteristic shape of rapidly increasing to a unique maxima and then slowly  
 461 tapering to 1, especially for polynomials  $f$  with high degrees. This suggests that  
 462 for each polynomial, there is an optimal level to achieve the greatest speedup.  
 463 In our tests (see Figure 2), we saw that both the optimal level and the value of  
 464 the corresponding greatest speedup factor depend on  $f$ . Moreover, we observed  
 465 that the achievable speedup tends to be bigger for  $E_4^{H'}$  than for  $E_3^{L'}$  and that it  
 466 increases with the degree of the polynomial  $f$ .

## 467 6 Conclusions and Future Work

468 We generalized the CL framework in order to achieve, for the first time, range  
 469 functions of arbitrarily high order of convergence. Our recursive scheme for such  
 470 constructions is not only of theoretical interest, but are practical as shown by our  
 471 implementations. Devising specific “best of a given order” functions like  $\square_{4,\ell}^{H'}f(I)$   
 472 is also useful for applications.

473 The amortized complexity model of this paper can be used to analyze many  
 474 subdivision algorithms in higher dimensions. Moreover, new forms of range primi-  
 475 tives may suggest themselves when viewed from the amortization perspective.

476 We pose as a theoretical challenge to explain the observed phenomenon of  
 477 the “unimodal” behavior of the  $\sigma(\ell)$  plots of Figure 2 and to seek techniques for  
 478 estimating the optimal recursion level that achieves the minimum time. More-  
 479 over, we would like to better understand why the size of the EVAL subdivision  
 480 tree increases with  $\ell$  in the case of sparse polynomials (see Table 1), while it  
 481 decreases for all other polynomials from our test suite.

482 Finally, we emphasize that strong box functions have many applications.  
 483 Another future work therefore is to develop the theory of strong box functions,  
 484 turning the abstract model of Section 2.2 into an effective (Turing) model in the  
 485 sense of [19].
