Less is more: refinement proofs for probabilistic proofs

Kunming Jiang, Devora Chait-Roth, Zachary DeStefano, Michael Walfish, and Thomas Wies
NYU Department of Computer Science, Courant Institute  *Now at Carnegie Mellon

Abstract. There has been intense interest over the last decade in implementations of probabilistic proofs (IPs, SNARKs, PCPs, and so on): protocols in which an untrusted party proves to a verifier that a given computation was executed properly, possibly in zero knowledge. Nevertheless, implementations still do not scale beyond small computations. A central source of overhead is the front-end: translating from the abstract computation to a set of equivalent arithmetic constraints. This paper introduces a general-purpose framework, called Distiller, in which a user translates to constraints not the original computation but an abstracted specification of it. Distiller is the first in this area to perform such transformations in a way that is provably safe. Furthermore, by taking the idea of “encode a check in the constraints” to its literal logical extreme, Distiller exposes many new opportunities for constraint reduction, resulting in cost reductions for benchmark computations of 1.3–50×, and in some cases, better asymptotics.

1 Introduction

Probabilistic proofs [7–9, 43–45]—PCPs, IPs, NIZKs, SNARKs, and so on—are fundamental in complexity theory and cryptography. They enable an untrusted prover to convince a verifier of some statement (for example, that a given computation $\Psi$, on specific input $x$, produces an alleged output $y$). In these protocols, the verifier does not inspect a classical witness to the truth of the statement (or re-execute $\Psi$) but instead checks an encoded proof probabilistically. Zero-knowledge variants allow the prover to keep some of the input to the computation—and the proof itself—hidden from the verifier. Astonishingly, the verifier’s checks are (in some protocols) constant-time, regardless of the size of the computation [7, 8, 42]. The appeal of these properties in emerging application areas (most notably, outsourced computation, blockchains, and their intersection) has fueled intense interest in implementations over the last 13 years. The results have included 20 orders of magnitude reduction in costs, deployment of SNARKs in cryptocurrencies [35, 61, 78, 96], and an explosion of frameworks [87, 90, 93].

Yet, probabilistic proofs are heavily limited in scalability, making them impractical for general-purpose use (the hype notwithstanding). One source of costs is the back-end, which is the complexity-theoretic and cryptographic proving machinery. The other source of costs is the front-end, which translates high-level computations into the format that the back-end works over. In most probabilistic proof implementations, that format is some variant of arithmetic constraints: equations over a finite field.

Unfortunately, not only must the prover perform cryptographic operations proportional to the number of constraints (often with memory requirements that scale similarly), but also constraints are a verbose way to represent computations (§2). For example, every iteration of a loop requires separate constraints—likewise with all branches of conditional statements. Inequality tests, when translated into constraints, are expensive. So is RAM.

The question that we ask and answer in this paper is: if back-end costs are here to stay and we are stuck translating computations to constraints, what can we do to mitigate costs? Any such technique should achieve:

- **Conciseness.** Compared to a naive translation of a computation $\Psi$, we want to produce a smaller set of constraints.
- **Coupling.** There should be a way for the prover to actually satisfy the alternate constraints, which is non-trivial, since they may not correspond to the individual program steps that the prover takes to execute $\Psi$.

These two requirements have been addressed, at least partially. The authors of almost all front-ends observe that translation from a high-level computation $\Psi$ need not result in constraints that simulate execution [26, 27, 30, 31, 51, 62, 71, 73, 75, 80, 82, 88, 91, 104] (§2). Rather, it suffices if the constraints are satisfiable iff the execution is valid. For example, consider a computation that invokes a quicksort subroutine. The naive approach is to compile quicksort into constraints. As an alternative [51, Appx. C], the prover can sort “outside the constraints”, with the constraints enforcing that (a) the output is a permutation of the input [20, 92], and (b) this permutation is sorted. The naive approach requires $O(n \log n)$ inequality tests while the alternative requires only $O(n)$ inequality tests (for adjacent elements in part (b)). As inequality tests dominate this computation, the improvement is substantial.

We call such a checker of required properties a widget. This generalizes “gadget” [62], which refers to constraints that have been written by hand; widgets can additionally be encoded in a higher-level language and then compiled to constraints. Widgets have been proposed for arithmetic and bitwise operations [80], multi-precision operations [51], storage [27, 70], concurrent access to state [82], cryptographic operations [15, 25, 27, 31, 61, 70, 78], recursive composition [25, 31, 53], and optimization problems [5].

Yet, to the extent that these works make arguments about the correctness of substituting a computation with a widget, none of them provides formal justification: it is entirely possible that there are wrong widgets out there! Note that any such bug, even in an application that satisfies the other two requirements, destroys soundness of the end-to-end application. Thus, we add a third requirement:

- **Correctness.** This is not about correctness of the translation to constraints, which is crucial and complementary, and has been studied [38]. Our focus on correctness in this paper is on substitutions (of computations by a widget) that happen “upstream” of compilation-to-constraints.
There is work addressing this third requirement [88] but at the expense of the first two (§7).

This paper contributes a framework, Distiller, that addresses all three of these desiderata (§4). Distiller takes the goals in reverse order: it starts with Correctness. For each class of computations, the user writes down a specification of the computation, and proves a formal relationship between the implementation and the specification. This justifies compiling the specification (rather than the implementation) to constraints. This relationship is ensured by representing both the implementation and the specification as transition systems and adapting ideas from the theory of refinement [32, 56, 57, 63, 97]. A refinement relates the externally observable behaviors of two transition systems, formalizing the notion of correct substitution. A proof of refinement then yields a blueprint for the prover to satisfy the abstract constraints (Coupling). For Conciseness, a consequence of Distiller and its generality is to expose new opportunities for constraint reduction: Distiller lets us take the idea of widgets to its literal logical extreme.

We apply Distiller to a series of examples (§5), including binary search, convex hull, maximal strongly connected components (MSC), and minimum spanning tree (MST). In particular, the solutions we obtain for the latter two problems may be of independent interest. Our widget for MSC bears some resemblance to the checker for Tarjan’s algorithm [85] proposed in prior work [24]. However, our solution builds on Dijkstra’s MSC algorithm [33] and is specifically designed to obtain an efficient representation in constraints. For MST, we introduce the idea of encoding operations on an amortized data structure as a kind of special-purpose memory; our widget exploits this encoding to check the execution of Kruskal’s algorithm [54] in a way that avoids the overhead of translating certain general-purpose computing structures (conditionals, loads, stores, loops with dynamic bounds) to constraints.

We implement and evaluate Distiller (§6). The system takes as input a program representing the implementation and specification transition systems, and generates outputs using two components. The first component partially automates the generation of refinement proofs relating the input transition systems. This component relies on additional user input in the form of proof annotations. The proofs can then be checked using the program verifier Viper [69]. Successful verification guarantees Correctness. The verification of our examples unveiled bugs that would have compromised Correctness in initial versions of two widgets. Once Correctness has been established, the second component enables Coupling by building on the Pequin toolchain [75]. This component produces two C programs that are provided as input to Pequin. One program expresses the part of the widget to be translated to constraints. The other program expresses the part to be computed outside the constraints. Pequin then translates the first program, executes the second program, and uses the obtained outputs to drive a probabilistic proof backend.

Finally, Conciseness: replacing an implementation by its specification does not guarantee more concise constraints. However, as we explain (§4–§5), we can often use Distiller to find, and establish the correctness of, an intermediate point between specification and implementation that does yield a substantial improvement (our work on MSC and MST, mentioned above, are examples of this). Concretely, in our examples, Distiller achieves reductions in constraint size ranging from small constant factors to asymptotic improvements for some problems, which for small problem instances already result in double-digit factors. Qualitatively, the more complex a computation, the more improvement Distiller generally yields. Computations with many memory accesses or searches of memory see particular benefit under Distiller.

Distiller is not perfect (§8). As a built system, its trusted computing base includes Pequin, Viper, and our own new translation front-end. However, this restriction is not fundamental.

The bottom line is that Distiller has taken a crucial step in improving front-ends: it has exhibited the logically most general way to exploit nondeterminism in arithmetic constraints, while doing so soundly, with performance improvements that range from good constants to orders of magnitude.

2 Background: applied probabilistic proofs

This section is intended to give just enough context for the rest of the paper. For a full, rigorous treatment of probabilistic proof implementations, see Thaler [87].

Back-end. In these setups, a back-end is a cryptographic or complexity-theoretic protocol between an untrusted prover \( P \) and a verifier \( V \) in which \( P \) convinces \( V \) that a given set of equations \( C \) has a solution.

In more detail, \( V \) and \( P \) (which are possibly probabilistic) agree on \( C \), as defined by a protocol, or defined by a user who invokes \( V \) and \( P \). The variables in \( C \) are elements in a finite field, typically \( \mathbb{F}_p \) (the integers mod \( p \)), where \( p \) is a large prime (128 bits or more). For many back-ends, \( C \) is required to be in RICS format [17, 18, 42, 73, 81]. RICS generalizes arithmetic circuits, which generalize Boolean circuits. We refer to such a set of equations as constraints.

\( V \) does not trust anything \( P \) says; \( P \) can follow an arbitrarily malicious strategy (though some protocols presume a computational bound on \( P \) and cryptographic hardness assumptions of one kind or another).

\( P \) wants to prove to \( V \) that \( P \) holds a solution, or satisfying assignment, \( z \) to \( C \)—but \( V \) does not want to receive \( z \), and \( P \) may wish to keep \( z \) hidden. Instead, \( P \) gives \( V \) a certificate, possibly revealed interactively, which \( V \) checks. The guarantees are:

- **Completeness**: If \( C \) is satisfiable, then a correct \( P \) makes \( V \) accept, always (regardless of random choices made by \( P \), \( V \), or by the user in an offline phase).

- **Soundness**: If \( C \) is not satisfiable, the probability that \( V \)'s checks pass is negligible (the probability is over random choices made by the verifier or by the user in an offline phase). Some applications require a more general property, Proof of Knowledge (PoK): if \( P \) does not have access to a satisfying \( z \) (even if \( C \) is satisfiable), then \( V \) accepts with negligible probability. Note that these properties hold regardless of \( P \)'s strategy.
• Zero knowledge: $\mathcal{V}$ gets no information about $z$ other than what can be deduced from the fact that $C$ can be satisfied.

Examples of recent back-ends are [22, 28, 29, 40, 41, 52, 53, 59, 64, 79, 94, 95, 100, 101]. These trade off different properties, including the nature of the cryptographic assumptions, noninteractivity, whether there is an offline phase, whether that phase has to be repeated each time the structure of $C$ changes, and so on. However, in all of these works, the costs have a major dependence on the number of constraints, $|C|$, and thus all of these works will benefit from improvements to front-ends.

Pipeline. Posit a user who cares about verifying the execution of some high-level computation $\Psi$, on some input $x$. $\mathcal{P}$ supplies $y$ that is purportedly $\Psi(x)$, and wants to convince some $\mathcal{V}'$, which is trusted by the user, that $y=\Psi(x)$. As a generalization, $\Psi$ can be a relation, so the goal is to prove that $y \in \Psi(x)$. Existing implementations have the following pipeline:

**Offline (one-time for $\Psi$):**

1. The user writes down the computation $\Psi$.
2. The user compiles $\Psi$ to constraints, $C$, over variables $X, Y, Z$, where $X$ and $Y$ are vectors of variables that represent the inputs and outputs. This compilation needs to respect Translation Fidelity: for any $x$ and $y$, $C(X=x, Y=y)$ is satisfiable (by some $Z=z$) if and only if $y=\Psi(x)$ (or $y \in \Psi(x)$). Here, $C(X=x, Y=y)$ means $C$ with $X$ bound to $x$ ($\mathcal{V}'$'s requested input) and $Y$ bound to $y$ (the purported output). As a small example, consider a computation that takes two inputs, computes their quotient (over a finite field, $\mathbb{F}_p$), and outputs that quotient plus 5. The corresponding constraints are: $C = \{X_1 = Z_1 \cdot X_2, Y = Z_1 + 5\}$. Notice that for all pairs $(x, y)$, $C(X=x, Y=y)$ is satisfiable (by some $Z_1 = z_1$) if $y = x_1 / x_2 + 5$.
3. The user runs any setup procedure required by the back-end.

**Online (for each $x, y$):**

4. Given a specific input $x$, $\mathcal{P}$ identifies a satisfying assignment $z$ to $C(X=x, Y=y)$. In the simplest case, $\mathcal{P}$ does so by directly executing $\Psi$.\(^1\)
5. $\mathcal{P}$ convinces $\mathcal{V}'$ that it has, or knows, a satisfying assignment to $C(X=x, Y=y)$. One property that we need from a pipeline is End-to-end Completeness: if $y = \Psi(x)$, then a correct $\mathcal{P}$ makes $\mathcal{V}'$ accept with probability 1. This property relies on Translation Fidelity and (the back-end’s) Completeness, together with the mechanics of Step 3.

Another essential property is End-to-end Soundness: if $y \neq \Psi(x)$, then $\mathcal{V}'$ rejects with overwhelming probability. This property relies on Translation Fidelity and (the back-end’s) Soundness.

Front-end. The front-end is Steps 1 and 3. We detail these steps below, incurring some textual debts to Buffet [91]. We focus on a compilation approach that we call the “ASIC approach”. The alternative is the “CPU approach”, which represents the execution of a CPU in constraints [15, 17–19, 103]. This results in much higher overhead [91].

\(^1\)Alternatively, $\mathcal{P}$ could possess auxiliary information that allows it to derive a satisfying assignment. A simple example is: $\Psi$ requires $\mathcal{P}$ to supply the pre-image of a given CRHF $H$ for a given digest, $d$. Then the input to $\Psi$ is $d$; the output is $M$. $\mathcal{P}$ is then establishing that $M \in H^{-1}(d)$, but we do not think of $\mathcal{P}$ as “executing” $H^{-1}$; indeed, $H^{-1}$ is presumed not to be efficiently computable.

Given a program, the compiler unrolls loops (each iteration gets its own variables), and converts the code to an intermediate form, for example static single assignment. The compiler then translates each line into one or more constraints [26, 27, 30, 31, 55, 71, 73, 75, 80, 91, 104]. Arithmetic and logical operations are concise. For example, the line of code $z3 = z2 + z1$ becomes $\{Z_3 = Z_2 + Z_1\}$. By contrast, each inequality test and bitwise operation costs $\Omega(w)$ constraints, where $w$ is the bit width of the relevant variables (these operations work by separating a finite field element into bits [80, Appx.C]; see also [17, 73, 81, 91]).

The combined set of constraints resulting from the line-by-line translation, and including RAM (see below), constitutes $C$.

RAM operations (which we refer to as LOAD and STORE but which encompass any situation where an array index is not known at compile time) translate into variables that feed into a separate RAM-checking computation. This computation can take several forms. One is based on permutation networks and coherence checks [16, 18, 77, 91]. Loosely speaking, the computation (a) converts a time-ordered transcript of RAM operations into an address-ordered transcript of RAM operations with ties broken by execution order, and (b) uses pairwise checks in the address-ordered transcript to ensure that every LOAD delivers the value from the most recent STORE. Other techniques include Merkle trees and memory checking [15, 23, 27], polynomial identity testing [103], set accumulators [70], or even a brute force switch statement that considers every possible index (this works at small scales, as for some blockchain statements). Regardless of the representation, each LOAD and STORE is costly, as the RAM-checking computation has a number of constraints proportional to $\Omega(n \cdot r)$, where $n$ is the number of operations, and $r$ is the address width (log of memory size).

Solving. To produce a satisfying assignment, $\mathcal{P}$ in most pipelines (but not all [71]; see §7) goes constraint by constraint. The solution to some constraints is immediate; for example, given the constraint $Z_3 = Z_2 + Z_1$, if $Z_1$ and $Z_2$ are already determined then the setting to $Z_3$ is mechanically derived. Other constraints require nondeterministic input from the prover. Recall our earlier example: $C = \{X_1 = Z_1 \cdot X_2, Y = Z_1 + 5\}$. Looking only at the constraint $X_1 = Z_1 \cdot X_2$, $\mathcal{P}$ knows $X_1$ and $X_2$ (they are inputs) but does not derive the setting of $Z_1$ by filling in other constraints. Rather, $\mathcal{P}$ computes $X_2^{-1}$ “outside” the constraints (for example, using repeated squaring to compute $X_2^{-2}$, which is $X_2^{-1}$ in $\mathbb{F}_p$) and then sets $Z_1$ as $X_1 \cdot X_2^{-1}$. Other examples are inequality tests, where $\mathcal{P}$ supplies the values of each bit, and RAM-checking, where $\mathcal{P}$ supplies the settings for switches in a permutation network. In these cases, the process of translation from $\Psi$ to constraints has to decorate certain constraints, to tell $\mathcal{P}$ how to solve them. (Decoration is known elsewhere as “annotation” [27, 71, 91], but later in this paper, we use “annotation” to mean something else.)

Widgets. Instead of representing certain operations directly in constraints, one can sometimes substitute a validity check, as with the sorting example in the Introduction; we call this validity check a widget. The Pipeline handles such substitution. Assume for simplicity that only one operation in the computation $\Psi$ has a widget, for example a single invocation of a sort() subroutine. Then Step 1 compiles the computation $\Psi$, but with the widget...
substituted for the direct operation. Meanwhile, Step 3 runs $\Psi$, with the direct operation. For this to work, the compiler must produce, and $\mathcal{P}$ must rely on, decorations. That is because $\mathcal{P}$ needs to connect the computation to the constraints, which no longer correspond to each other line-by-line.

When widgets enter the picture, achieving End-to-end Soundness and End-to-end Completeness requires an additional condition beyond the three that we have mentioned, namely Translation Fidelity, and (back-end) Completeness and Soundness. That additional condition is Correctness, from Section 1. Section 3 describes this condition informally; a precise definition requires machinery that we will build up in Section 4.

Costs and accounting. This paper’s primary metric is $|\mathcal{C}|$. That is for two reasons. First, all back-ends in the literature impose costs on $\mathcal{P}$ (and, depending on the protocol, on $\mathcal{P}'$) that are at least linear in the number of constraints, $|\mathcal{C}|$. Second, these costs typically dominate the cost to $\mathcal{P}$ of executing and solving (Step 3); thus, even though $\mathcal{P}$ executes the underlying computation, doing so contributes only negligibly to costs.

For concreteness, we sometimes assume the widely-used Groth16 backend [47, 62]. In Groth16, certificate size is constant (128 bytes) and $\mathcal{P}'$ runs in constant time, however, the running time for $\mathcal{P}$ and for the setup phase are $O(|\mathcal{C}| \cdot \log |\mathcal{C}|)$. Because of this and memory bottlenecks from the access pattern, single-machine Groth16 provers are highly limited in the size of the computation that they can handle. There are works that take advantage of multiple machines [98] and heterogeneous hardware [102] to try to overcome these bottlenecks, but they too are limited. The bottom line is that every work in this research area will benefit from constraint sets with fewer constraints.

3 Motivating example: merging sorted lists

As noted in the introduction, an application of probabilistic proofs, at least in principle, is outsourcing computation. Those computations need not be “cryptographic”. In fact, the mere act of outsourcing invites probabilistic proof machinery: a proof gives assurance that another entity executed correctly. Accordingly, our examples throughout this paper will have an algorithmic flavor, rather than employing cryptography. In particular, zero-knowledge guarantees provided by the back-end will be irrelevant. However, this is not fundamental, as zero-knowledge properties typically come for free in the back-end, and the Distiller framework applies just the same to cryptographic computations.

As an example algorithmic computation, consider $\text{merge}$, which takes as input multiple sorted lists with unique elements (unique across all lists) and outputs a sorted union of the elements. An example implementation of $\text{merge}$, which we denote $T_5$, is in Figure 1. When translated, merge comprises a number of constraints proportional to $L \cdot (\sum_k A_k \cdot \text{len})$, because of the nested loops on lines 9 and 11.

Observe that $\text{merge}$ is computing its result. But in the setup of probabilistic proofs, the goal is to provide a proof about some alleged, exogenously-computed output. Thus, the set of constraints could instead check that a specification is met. We are interested in how to perform such a substitution systematically, meaning that the requirements in Section 1 are met.

A natural starting point is to translate the weakest logical specification (WLS) of merge that still expresses functional correctness: intuitively, one expects that logically weaker specifications “enforce less” and thus should yield smaller constraints when translated. Informally, the WLS is: “$\text{merge}(L_0, \ldots, L_{L-1}, B)$ ($T_5$). The precondition of $\text{merge}$ requires that the $A_k$ are strictly sorted and their elements pairwise distinct. Also, there must be enough physical space in $B$ to store the elements of all $A_k$.

![Figure 1: Pseudocode for the computation $\text{merge}(L_0, \ldots, L_{L-1}, B)$](image)

Figure 1: Pseudocode for the computation $\text{merge}(L_0, \ldots, L_{L-1}, B)$ ($T_5$). The precondition of $\text{merge}$ requires that the $A_k$ are strictly sorted and their elements pairwise distinct. Also, there must be enough physical space in $B$ to store the elements of all $A_k$. To read the pseudocode, note that the keyword $\text{havoc}$ denotes a nondeterministic choice, while $\text{assume}$ constrains choices. Concretely, when this pseudocode is compiled to $C_{T_5}$ ($\S 2$), $\text{havoc}$ statements become free variables that the prover supplies while $\text{assume}$ statements become constraints that enforce the given statement. The specification uses $\text{for}$, which (logically) means bounded universal quantification, and (mechanically) unrolls and repeats the enclosed requirements.

In Figure 2, lines 4–12 constrain $B$ to be sorted (in increasing order), and enforce that $B \subseteq \bigcup_j A_j$. In particular, for each position $i$ in $B$, the prover nondeterministically supplies which list ($k_i$) contributes to the $i$th position, and which index in that list ($j_i$) holds the contributed element. For the other direction, lines 13–20 specify that $\bigcup_j A_j \subseteq B$.

But how does the prover supply these values? Ideally they
We formalize our framework in terms of which we call would result from simply executing the original computation.

### 4 Framework

We formalize our framework in terms of transition systems, which provide a uniform formalism for representing both implementations and their specifications. From a semantic perspective, a transition system $T$ defines a language $L(T)$, which contains for each execution trace $\sigma$ of $T$, a sequence of observations $o(\sigma)$ made about how $T$ interacts with its environment during the execution. These observations may for instance encompass I/O, network traffic, etc.

We relate transition systems in terms of their languages. This allows us to formally capture when the execution of one transition system behaves like the execution of another, from the perspective of an external observer.

#### 4.1 Transition systems and refinement

In our formalization, we adapt the classical setup of Abadi and Lamport [1]. A transition system $T = (\Sigma, \Theta, \Delta, O, \alpha)$ consists of a set of states $\Sigma$, a nonempty set of initial states $\Theta \subseteq \Sigma$, a set of transitions $\Delta \subseteq \Sigma \times \Sigma$, a set of observations $O$, and an observation function $\alpha : \Sigma \rightarrow O$. Intuitively, the function $\alpha$ formalizes which aspects of a given state are observable. When $T$ is known, we denote a transition $(s, s') \in \Delta$ by $s \rightarrow s'$ and say $s$ steps to $s'$. We also call $s'$ a successor of $s$.

Example 4.1. We illustrate with our motivating example (§3). We can regard $T_I$ (Fig. 1) as defining a transition system $(\Sigma, \Theta, \Delta, O, \alpha_I)$, as follows. The states $\Sigma$ of $T_I$ are mappings from program variables to values. For $s \in \Sigma$, we denote by $s.x$ the value of program variable $x$ in $s$. We sometimes write $x$ for a value of the program variable $x$ when the state $s$ is unspecified. We write $s[x \mapsto v]$ to denote the new state obtained from $s$ by updating the value of $x$ to $v$ and keeping the values of all other program variables unchanged. The program variables include a dedicated variable $pc$ storing the value of the program counter, which ranges over the control locations $\ell_0, \ldots, \ell_4$. (For simplicity of exposition, we are treating the execution of a basic block, such as one iteration of a non-nested loop, as a single transition.)

The observations $O$ of $T_I$ are the values of the input arrays and output array at the program start and return. Intuitively, these are the values that an external user can observe from the program. All intermediate program states of the computations are unobservable, which we denote by the special observation $\tau$. Formally, we define $O$ using the following grammar:

\[
O ::= \text{in}(L, A_0, \ldots, A_{L-1}, B) \mid \text{out}(L, A_0, \ldots, A_{L-1}, B) \mid \tau
\]
The observation function $\alpha : \Sigma \rightarrow O$ is then defined as follows:

$$
\alpha(s) = \begin{cases} 
\text{in}(s.L,s.A_0,\ldots,s.A_{(c-1)},s.B) & \text{if } s.pc = c_0 \\
\text{out}(s.L,s.A_0,\ldots,s.A_{(c-1)},s.B) & \text{if } s.pc = c_4 \\
\tau & \text{otherwise}
\end{cases}.
$$

The transitions $\Delta$ of $T_I$ are obtained from the program description in the expected way. For instance, the body of the loop at control location $c_1$ yields all transitions $s \rightarrow s'$ such that $s.pc = c_1$, $s.k < s.L$, and

$$
s' = s[\text{len} \mapsto s.\text{len} + s.A_{(s.k)}] \cdot \text{len}[k \mapsto s.k + 1].
$$

The set of initial states $\theta$ consists of all states $s$ that satisfy the precondition of $T_I$ (Figure 1). We assume that this precondition is specified by a formula $\phi_{\text{pre}}$. That is, $\phi_{\text{pre}}$ states that $pc = c_0$, and that the arrays $A_k$ are sorted in strictly increasing order and its elements pairwise distinct. We write $s \models \phi_{\text{pre}}$ to indicate that $s$ satisfies $\phi_{\text{pre}}$.

An infinite sequence of states $\sigma$ is called an (execution) trace of $T$ if it starts in an initial state and respects $T$’s transition relation: formally, $\sigma_0 \in \theta$ and for all $i \geq 0$, either $\sigma_i$ steps to $\sigma_{i+1}$ or $\sigma_i = \sigma_{i+1}$ and $\sigma_i$ has no successors in $\Delta$. If $\sigma_i = \sigma_{i+1}$, we say that $\sigma$ stutters in step $i$. A terminating execution of $T$ corresponds to a trace that stutters forever in its final state. By abuse of notation, we write $\alpha(\sigma)$ to denote the sequence of observations obtained by applying $\alpha$ pointwise to the states in $\sigma$. We denote the set of all traces of $T$ by $\text{traces}(T)$.

Let $\not\models$ be the function that maps a sequence $\sigma$ to the sequence obtained from $\sigma$ by replacing all repeated consecutive copies of elements by a single copy, for example, $\not\models((0,0,1,1,2,3,3,3,3)) = (0,1,2,3)$.

The language of $T$, denoted $L(T)$, is defined by applying $\alpha$ pointwise to each trace in $\text{traces}(T)$ and then removing stuttering. The intuition for removing stuttering is that we want to capture only the observable behavior: stuttering steps correspond to unobservable internal computation steps. Formally, we define the sequence of observations $o(\sigma)$ made from a trace $\sigma$ as $o(\sigma) \defeq \not\models(\alpha(\sigma))$ and then let

$$
L(T) \defeq \{ o(\sigma) | \sigma \in \text{traces}(T) \}.
$$

Example 4.2. In the motivating example (§3), the language of the transition system $T_I$ is simply

$$
L(T_I) = \{ (s,\tau,s') | s \models \phi_{\text{pre}} \land s' \models \phi_{\text{post}} \}.
$$

Here, the precondition $\phi_{\text{pre}}$ is as defined above. The postcondition $\phi_{\text{post}}$ states that $pc = c_4$, $B$ is sorted in strictly increasing order, and the set of elements of $B$ is equal to the union of the set of elements of the arrays $A_k$. The single $\tau$ in each observation sequence in $L(T_I)$ summarizes all intermediate states of the computation.

A transition system $T_I$ refines another transition system $T_S$ iff $L(T_I) \subseteq L(T_S)$. This definition captures the idea that from the perspective of an external observer, every execution of $T_I$ behaves like some execution of $T_S$. Typically, we think of $T_S$ as the specification and $T_I$ as the implementation. We denote a refinement relationship by $T_I \leq T_S$.

A classical approach to proving refinement relationships is to construct a refinement mapping. Formally, a refinement mapping between $T_I$ and $T_S$ is a function $r : \Sigma_I \rightarrow \Sigma_S$ such that

1. $r(\theta_I) \subseteq \theta_S$,
2. $\forall s \in \Sigma_I, \alpha_I(s) = \alpha_S(r(s))$, and
3. $\forall s, s' \in \Sigma_I, r(s) \rightarrow r(s')$ or $r(s) = r(s')$.

The first property states that $r$ maps the initial states of $T_I$ to those of $T_S$. The second property states that the observations computed from states are preserved by $r$. The third property states that every transition in $\Delta_I$ is matched by a corresponding transition in $\Delta_S$ under $r$ or by a stuttering step. Together, these properties capture the intuition that the relationship between a refinement and its specification is that the specification abstracts steps that are “internal” to the implementation.

Once it has been established that $r : \Sigma_I \rightarrow \Sigma_S$ is a refinement mapping, $T_I \leq T_S$ follows: given a trace $\sigma_I$ of $T_I$, the sequence $r(\sigma_I)$ is a trace of $T_S$ (modulo stuttering). Moreover, $r(\sigma_I)$ makes the same observations as $\sigma_I$, i.e., $\not\models(\alpha_I(\sigma_I)) = \not\models(\alpha_S(r(\sigma_I)))$. Hence, the existence of $r$ establishes that $T_I$ refines $T_S$.

We write $T_I \leq_r T_S$ to indicate that $r$ is a refinement mapping between $T_I$ and $T_S$. An important property that we will use freely later is that refinement mappings compose: $T_1 \leq_r T_2$ and $T_2 \leq_r T_3$ implies $T_1 \leq_r T_3$.

### 4.2 Refinement-based widgets

We can now use the language of transition systems to recast Steps 0, 1, and 3 in Section 2 and explain how widgets are conventionally used to modify these steps. We start from a given transition system $T_I$ and a property $\phi \subseteq O^\omega$ specifying the observation sequences of interest (Step 0). The problem is for the prover $P$ to convince the verifier $V$ that $L(T_I) \cap \phi$ is nonempty. Here, the property $\phi$ will, in particular, ensure that the considered observations are restricted to those that are bound to the specific input $x$ and alleged output $y$. However, $\phi$ may impose additional requirements on the observation sequences that are of interest to $V$. The conventional approach is then to first translate $T_I$ into constraints $C_{T_I}(\phi) = C_{T_I} \land C_{T_I}^{-1}(\phi)$. We elide the definition of $C_{T_I}^{-1}(\phi)$. In the context of the steps in Section 2, it is simply $X = x \land Y = y$. The translation guarantees that $C_{T_I}(\phi)$ is satisfiable iff $o(\sigma_I) \in L(T_I) \cap \phi$ for some $\sigma_I$ (Step 1). The prover then executes $T_I$ on the specified input $x$ to obtain such a $\sigma_I$ and derives from it the desired satisfying assignment (Step 3).

The conventional use of a widget is then to replace the constraints $C_{T_I}$ by a smaller set of constraints $C_{T_W}$. The prover still executes $T_I$ to yield $\sigma_I$, but uses $\sigma_I$ to compute a satisfying assignment for $C_{T_W}(\phi)$. A crucial shortcoming of this approach is that replacing $T_I$ by $T_W$ is not formally justified. In particular, there is no guarantee that the existence of a satisfying assignment for $C_{T_W}(\phi)$ implies the nonemptiness of $L(T_I) \cap \phi$, potentially compromising the soundness of the proof system. Moreover, there is no systematic approach to compute a satisfying assignment for $C_{T_W}(\phi)$ from $\sigma_I$. We use the notion of refinement to address both of these shortcomings.
First, we change the problem setup as follows. The new Step 0 is to write down transition systems $T_S$, $T_E$, and $T_I$, as well as refinement mappings $r$ and $o$ such that $T_I \preceq_r T_E \preceq_o T_S$. This is our formal definition of Correctness (§1): a widget represented as $T_E$ is Correct if it satisfies the refinement chain $T_I \preceq_r T_E \preceq_o T_S$. Now, the problem is for the prover $P$ to convince the verifier $V'$ that $\mathcal{L}(T_I) \cap o \neq \emptyset$. That is, $\mathcal{V}'$ is only interested in $T_S$, the weakest specification; the transition systems $T_E$ and $T_I$ are merely a means to an end to solve the problem. $T_E$ then plays the role of $T_W$ above. The new Step 1 is to translate $T_E$ and $o$ into constraints $\mathcal{C}_{T_E}(\sigma)$. The new Step 3 is for $P'$ to execute $T_I$ on $x$ (obtaining $o(\sigma_I) \in \mathcal{L}(T_I) \cap o$), to use $r$ to compute a trace $r(\sigma_I)$, and finally to use $r(\sigma_I)$ to compute a satisfying assignment for $\mathcal{C}_{T_E}(\sigma)$.

Observe that $T_E \preceq_o T_S$ implies that if $o(\sigma_E) \in \mathcal{L}(T_E) \cap o$ for some $\sigma_E$, then $o(q(\sigma_E)) \in \mathcal{L}(T_S) \cap o$. Hence, assuming Translation Fidelity, if $\mathcal{C}_{T_E}(\sigma)$ is satisfiable, then $\mathcal{L}(T_S) \cap o$ is nonempty. This ensures the soundness of the approach. Similarly, $T_I \preceq_r T_E$ means that if $o(\sigma_I) \in \mathcal{L}(T_I) \cap o$, then $o(r(\sigma_I)) \in \mathcal{L}(T_E) \cap o$ and, hence, $\mathcal{C}_{T_E}(\sigma)$ is satisfiable. This ensures the completeness of the approach.

A difference between proving $T_I \preceq_r T_E$ and $T_E \preceq_o T_S$ is that $q$ need not be explicit. That is, although End-to-end Soundness requires that if $\mathcal{C}_{T_E}(\sigma)$ is satisfiable then so is $\mathcal{C}_{T_E}(\sigma)$, the actual satisfying assignment to $\mathcal{C}_{T_E}(\sigma)$ is not used explicitly. Consequently, $T_E \preceq T_S$ can be established by means other than refinement mappings, for example a proof based on simulation relations [66, 72, 89].

We note that the approach also applies in the special case where $T_S = T_E$. Though, generally, the crux is to find a suitable $T_E$ in between $T_S$ and $T_I$ that yields a reduction in the constraint size relative to both $T_S$ and $T_I$.

Constructing refinement mappings. It remains to show how to construct refinement mappings. We demonstrate this with the merge computation as a guiding example, using general principles inspired by refinement calculi such as [65, 67, 68]. These principles apply broadly (Section 5 contains further examples).

Our first step is to construct a refinement mapping $r$ between the transition system $T_I$ of the merge computation (Fig. 1) and its intermediate specification $T_E$ (Fig. 3). As we will explain below, $r$ can then be used to obtain a satisfying assignment for the constraints $\mathcal{C}_{T_E}$ from a given execution of $T_I$, enabling more efficient verification of that execution. In a second step, we then show that the intermediate specification $T_E$ refines the naive specification $T_S$.

To prove $T_I \leq T_E$, we divide the construction of the refinement mapping into three steps by deriving two auxiliary transition systems $T_{IE}$ and $T_{IE}'$ that yield a refinement sequence $T_I \leq T_{IE} \leq T_{IE}' \leq T_E$. Intuitively, the auxiliary transition systems couple $T_I$ and $T_E$ so that they are executed together.

A transition system $T_E$ refined by an implementation $T_I$ will typically involve nondeterministic (havoc, see §3) assignments to program variables that do not appear in the implementation. In our example of the merge computation, these are the assignments to $k_i$ and $j_i$ in Figure 3 (lines 8 and 10). The execution of $T_E$ can proceed only if the value chosen by each nondeterministic assignment satisfies the constraints imposed by the subsequent

```cpp
void merge (L,A_0,...,A_{L-1},B) {

  \ell_S: int[L] curr = \{0\};
  int len, running_min, kstar, k_i, j_i;
  bool found;
  len = 0;
  \ell_I: for (int k = 0; k < L; k++) {
    len += A_{k}.len;
    B.len = len;
    assume B.len == \sum_{i=0}^{k} A_{k}.len;
    \ell_E: for (int i = 0; i < B.len; i++) {
      found = false;
      for (int k = 0; k < L; k++) {
        if (curr[k] < A_{k}.len && (!found ||
           A_{k}[curr[k]] < running_min)) {
          running_min = A_{k}[curr[k]];
          kstar = k;
          found = true;
        }
      }
    }
    return;
  }
}
```

Figure 4: Pseudocode for the transition system $T_{IE}$. The prover will execute the black and blue code ($T_{IE}$) instead of $T_I$. The values in blue are used to create an assignment to the nondeterministic variables occurring in the constraints obtained from $T_E$ (the red `assume` statements).

**assume** statements. A key step in the refinement proof is therefore to show that such values can be obtained from the trace $\sigma_I$. We make this step explicit in the construction of the intermediate transition system $T_{IE}$. This transition system augments $T_I$ with those variables unique to $T_E$ as well as assignments to those variables that determine the desired values to be chosen for the nondeterministic assignments in $T_E$. In our example, this augmentation can be seen in lines 3, 21, and 23 shown in blue in Figure 4.

Observe that the assignments to $k_i$ and $j_i$ in $T_{IE}$ of our example depend only on the original program variables of $T_I$. Moreover, the variables do not interfere with the other parts of the transition system in any way. Such auxiliary variables that are used only for the purpose of proving a refinement relation are sometimes referred to as ghost variables. Conveniently, if adding ghost variables to a transition system $T$ results in $T'$, then $T \leq T'$ [65]; thus $T_I \leq T_{IE}$.

In the context of program translation for probabilistic proofs, augmenting an implementation with ghost variables is not only useful for proving the refinement between $T_I$ and $T_E$. The system $T_{IE}$ also instructs the prover how to obtain the satisfying assignment for the constraints $\mathcal{C}_{T_E}$. That is, the prover will actually execute $T_{IE}$ instead of $T_I$.

The next step in our construction is to augment $T_{IE}$ with the **assume** statements in $T_E$ that constrain the values chosen for the
nondeterministic assignments. We call the resulting transition system \( \tilde{T}_E \). In our merge example, \( \tilde{T}_E \) is shown in Figure 4 with the added assume statements highlighted in red (lines 8, 20, 22, and 24).

Establishing the refinement \( T_E \leq \tilde{T}_E \) follows a generic construction. We first show that the added assume statements express invariants of \( T_E \). That is, the assumed expressions must always evaluate to true in \( T_E \), at the appropriate program points. In Appendix A [48], we discuss this step of the proof in more detail with regards to the merge computation. Once the invariants have been established, \( T_E \leq \tilde{T}_E \) follows, by simply using the identity function on the states of \( \tilde{T}_E \) as the refinement mapping.

Finally, we observe that \( T_E \) can be obtained from \( \tilde{T}_E \) by abstracting all program variables that appear in \( T_I \) but not in \( T_E \). For our merge example, this amounts to removing the loops at locations \( \ell_1 \) and \( \ell_3 \) in \( \tilde{T}_E \), and replacing the assignments on lines 7, 19, 21, and 23 that depend on the abstracted program variables by havoc commands.

Abstracting program variables in this systematic manner again yields a refinement by construction. The refinement mapping changes the value of the program counter in the expected way. For instance, the refinement mapping in our example coalesces locations \( \ell_2 \) and \( \ell_3 \) to \( \ell'_3 \) and maps all other locations \( \ell_i \) to \( \ell'_i \). The values of the remaining program variables that are common to \( \tilde{T}_E \) and \( T_E \) are preserved by the refinement mapping. This concludes the proof of \( T_I \leq T_E \).

It remains to argue that \( T_E \) refines \( T_S \). One can generally apply the above technique again, to construct an appropriate refinement mapping. In particular, one can show that the following property is an invariant at the end of the for loop in \( T_E \) (Fig. 3):

\[
\forall k, j : \ 0 \leq k \land k < L \land 0 \leq j \land j < A_k.\text{len} \implies \\
\exists i : \ 0 \leq i \land i < B.\text{len} \land A_k[j] = B[i]
\]

The second for loop at lines 13 to 20 of \( T_S \) (Fig. 2) establishes exactly the same property.

**Systems view.** An end-to-end system view of Distiller is as follows. At compile-time the user provides a weakest specification \( T_S \), an effective specification \( T_E \), and a computation \( T_I \) (the new Step 0 in Section 2). One must then show that the refinement relationships \( T_I \leq T_E \) and \( T_E \leq T_S \) hold. These proofs can be done by the user outside of the system or the system aids the user by (partially) automating the proofs.

Such a refinement proof (say, \( T_I \leq T_E \)) can be constructed generically in the following way. First, one augments \( T_I \) with the necessary ghost variables (yielding \( T_E \)) to obtain \( T_I \leq T_E \). Then one adds the invariants needed to properly constrain the nondeterministic assignments in \( T_E \) (yielding \( \tilde{T}_E \)) to obtain \( \tilde{T}_E \leq T_E \). To take the final step to \( T_E \), one abstracts away all variables that are found in \( T_E \) but not \( T_E \) to obtain \( \tilde{T}_E \leq T_E \). One proceeds similarly for \( T_E \leq T_S \).

\( \tilde{T}_E \) is a coupling of \( T_I \) and \( T_E \) that makes explicit how the havoc ghost variables in \( T_E \) are computed from \( T_I \). \( \tilde{T}_E \) is then the input to an augmented front-end that splits \( \tilde{T}_E \) into \( T_E \) and \( T_E \). It then compiles \( T_E \) to constraints \( C_{T_E} \) (the new Step 1). For each invocation of the probabilistic proof protocol (the new Steps 3 and 4), the prover runs \( T_E \) and feeds its values back in to get a satisfying assignment to \( C_{T_E} \).

**Figure 5:** Improvement for all examples based on theoretical analysis on large inputs. For improvements where \( T_E \) has asymptotically fewer constraints than \( T_I \), we provide the complexity of the improvement; otherwise we provide a constant factor. \( L \) in Merging is the number of lists. \( n \) in Binary Search is the length of the array. \( n \) in 2D Convex Hull is the total number of nodes, and 2D Convex Hull* is the case where the nodes in the convex hull are marked instead of returned in a list.

Note that \( T_E \leq T_S \) is needed for End-to-end Soundness (every satisfying assignment to \( C_{T_E} \) encodes an element of \( L(T_S) \)) while \( T_I \leq T_E \) is needed for End-to-end Completeness (a satisfying assignment to \( C_{T_E} \) can be obtained from \( T_I \)).

**5 Examples**

We have applied the Distiller framework to the problems in Dijkstra’s classic book *A Discipline of Programming* [33]. We chose this source for two reasons. First, it discusses algorithms for a diverse set of problems. Second, Dijkstra develops his algorithms iteratively, starting from a formal problem specification. This approach helps to identify suitable intermediate transition systems \( T_E \) that yield an efficient translation to constraints.

Our evaluation considers 11 of the 14 problems discussed in Dijkstra’s book. The three problems we have omitted are “Updaging a sequential file” (Chapter 15), “The problem of the smallest prime factor of a large number” (Chapter 20), and “The problem of the most isolated villages” (Chapter 21). We also have simplified the problem of computing the convex hull in three dimensions (Chapter 24) to the two-dimensional case.

For all the problems that we have considered, we are able to obtain significant reductions in the size of the generated constraints (Fig. 5). In some cases, the scale factor of the reduction grows asymptotically with the problem instance size.

In the following, we discuss a selected subset of the considered problems in detail. We explain \( T_S \), \( T_E \), and \( T_I \) for these problems, provide a qualitative analysis that explains the expected reduction in constraint size, and explain the key insights behind the refinement proofs.
int find_min(n, A, B) {
    int min = A[0]; int p = 0;
    \( \ell_0: \) for (int i = 0; i < n; i++) {
        if (A[i] < min) {
            min = A[i]; p = i;
        }
    }
    bool found = false;
    \( \ell_1: \) for (int i = 0; i < n; i++) {
        assume min <= A[i];
        if (A[i] == min) {
            B[i] = 1; assume B[i] == 1;
            found = true;
        } else {
            B[i] = 0; assume B[i] == 0;
        }
        assume found;
    }
    return min;
}

Figure 6: Pseudocode for \( T_I \) of Find Min. The code in red is the augmentation needed for proving \( T_I \leq T_E \).

5.1 Find Min

Given a non-empty array \( A \) of length \( n \), the problem is to find its smallest element, \( \text{min} \), and mark all occurrences of the minimum using another array \( B \). More precisely, there must exist an index \( p \) such that the following conditions hold:

1. \( 0 \leq p < n \) and \( \text{min} = A[p] \),
2. for each \( i \in [0, n) \), \( \text{min} \leq A[i] \),
3. for each \( i \in [0, n) \), \( B[i] = \min \{A[i], \text{min} \} \).

\( T_S \) encodes this specification by nondeterministically choosing \( \text{min}, \) each \( B[i] \), and \( p \). It uses two loops that iterate over \( A \) to enforce conditions 2 and 3.

\( T_I \) is shown in Fig. 6 (without the code in red, which we will discuss later). It also requires two loops: \( \ell_0 \) to compute \( \text{min} \), and \( \ell_1 \) to compute the \( B[i] \). Comparing \( T_I \) and \( T_S \), we note that the two loops in \( T_I \) and \( T_S \) have exactly the same costs. However, \( T_S \) performs an additional dynamic LOAD, namely \( A[p] \), to enforce Condition 1. Hence, \( C_{T_S} \) incurs the extra cost of RAM initialization, which performs \( n \) STOREs to write \( A \) into the memory, and is therefore larger than \( C_{T_I} \).

However, we can do better than either \( T_S \) or \( T_I \). First, observe that unlike in \( T_I \), we can merge the two loops in \( T_S \) for conditions 2 and 3 into a single loop because \( \text{min} \) can be chosen nondeterministically upfront. Compared to \( T_I \), this saves one of the two inequality tests \( i < n \) that \( C_{T_I} \) would otherwise include for each iteration of the two loops. Furthermore, we can eliminate the LOAD \( A[p] \) in Condition 1 of \( T_S \) by introducing an auxiliary variable \( \text{found} \) that indicates whether \( \text{min} \) has been encountered at least once in the loop that checks conditions 2 and 3. The pseudocode of the resulting \( T_E \) is shown in Fig. 7 (excluding the blue code, which we will use later to establish that \( T_E \) refines \( T_S \)).

Thus, \( C_{T_E} \) needs only \( 2 \cdot n \) inequality tests, saving \( 1/3 \) over \( C_{T_I} \). Since the encoding of inequality tests dominates the size of the generated constraints, we observe a similar constant factor improvement in the overall constraint size.

Turning to the refinement proofs, if we add the red code in Fig. 6 to \( T_I \), we obtain the augmented transition system \( \hat{T}_E \) for showing \( T_I \leq T_E \) (see §4.2). Recall that the main part of the refinement proof is to show that the added assume statements in \( \hat{T}_E \) coming from \( T_E \) always succeed. We focus on the assume on Line 18, which is the most interesting one. Observe that the loop at \( \ell_0 \) ensures \( 0 \leq p < n \land A[p] = \text{min} \) after the loop has terminated. Using this fact, we can then establish the loop invariant \( i < p \lor \text{found} \) for the second loop at \( \ell_1 \). This then allows us to prove that the assume statement on Line 18 is safe.

Next consider the refinement \( T_E \leq T_S \). Adding the blue code in Fig. 7 to \( T_E \) yields an augmented transition system \( \hat{T}_{ES} \) for the refinement proof \( T_E \leq T_S \). We focus on showing that \( T_E \) ensures Condition 1. (The other two conditions follow immediately from the loop in \( T_E \).) To this end, we can establish the loop invariant \( \text{found} = 0 \lor (0 \leq p < n \land A[p] = \text{min} \) for the loop at \( \ell'_1 \). Together with Line 14, this implies that adding the assume on Line 15 is safe. This line then establishes Condition 1.

We note that we would not be able to improve over \( T_I \) if the array \( A \) was guaranteed to have a single minimum, or if we were satisfied with finding any of the minimums in \( A \). The loops at \( \ell_1 \) and \( \ell'_1 \) would be unnecessary.

5.2 Binary Search

int find_min_efficient(n, A, B) {
    int min, p;
    \( \ell'_0 \): havoc min;
    bool found = false;
    \( \ell'_1 \): for (int i = 0; i < n; i++) {
        assume min <= A[i];
        if (min == A[i]) {
            havoc B[i]; assume B[i] == 1;
            found = true; p = i;
        } else {
            havoc B[i]; assume B[i] == 0;
        }
    }
    assume found;
    assume 0 <= p < n && A[p] == min;
    return min;
}

Figure 7: Pseudocode for \( T_E \) of Find Min. The code in blue is the augmentation needed for proving \( T_E \leq T_S \).

Given a sorted array \( A \), the bounds \( l, r \) of a possibly empty segment in \( A \), and a value \( x \), the problem is to compute \( i \) such that \( l \leq i \leq r \) and \( A[i] = x \). If no such \( i \) exists, return \( i = -1 \).

\( T_S \) for this problem checks \( i \) according to the specification above. That is, if \( i \neq -1 \), \( T_S \) checks that \( l \leq i \leq r \) and \( x = A[i] \), otherwise it iterates over \( A[l \ldots r] \) and checks that the segment does not contain \( x \). \( T_I \) is based on standard binary search.

For our cost analysis we focus on the number of LOAD operations, which is the largest contributor to the size of the generated constraints. In the worst case, \( T_I \) performs \( \log(n) \) LOAD operations to search through the segment \( A[l \ldots r] \) where \( n = r - l \). In contrast, \( T_S \) performs \( n + 1 \) LOAD operations in the worst case.
That is, $T_3$ is asymptotically worse than $T_2$.

We can do better by exploiting that $A$ is sorted. Introducing an auxiliary value $s$, we divide the specification for the case when $x$ is not present ($i = -1$) into four subcases while retaining the specification for the case when $i\neq -1$. The refined specification becomes:

1. If $i = -1$, then $l = r$ or $x < A[l]$ or $x > A[r - 1]$ or ($l \leq s < r - 1 \& \& A[x] < x < A[s + 1]$).
2. else $l \leq i < r \& \& A[i] = x$.

$T_E$ is the direct encoding of this case analysis. It performs a constant number of LOAD operations, achieving an asymptotic improvement over $T_I$. We note that if the search is viewed as a standalone program, then this improvement is overshadowed by the cost of storing the array segment into RAM, which is linear in $n$. However, if the search is executed many times or viewed as a subroutine, then the RAM initialization can be amortized.

For proving $T_E \leq T_S$, observe that each of the subcases of Condition 1 implies that $x$ cannot be present anywhere in the segment. For the last three cases, the proof relies on the precondition that $A$ is sorted in strictly increasing order. For proving $T_I \leq T_E$, recall that binary search iteratively shrinks a subsegment $A[l \ldots r]$ of $A[1 \ldots r]$ that may still contain $x$. This process continues until the subsegment converges to a single point $l' = r'$, which is the index of the least element larger than $x$. In the nontrivial case where $l \neq r$ and $x$ is not present in the segment but within the range of values defined by $A[l]$ and $A[r - 1]$, we define $s = l' - 1$ for the final point $l' = r'$. Then $s$ is the index that satisfies the last disjunct in Condition 1.

### 5.3 2D Convex Hull

Given a set of points $P = \{p_0, \ldots, p_{n-1}\} \subseteq \mathbb{Z}^2$ with $n > 1$, assume no three points are on the same line, the problem is to find all points in $P$ that lie on the convex hull of the set.

We additionally require $P$ to satisfy the precondition of Graham Search [46], a popular algorithm that solves the 2D Convex Hull problem. Specifically, $p_0$ has the smallest $y$ coordinate among all points in $P$, and the greatest $x$ coordinate among all points in $P$ with the same $y$ coordinate as $p_0$. The remaining points are sorted in counterclockwise order when using $p_0$ as a reference point. In other words, for each $i \in (0, n)$, let $L_i$ be the line passing through $p_0$ and $p_i$. Then intersect $L_i$ with a horizontal line at $p_0$ and define $\angle_i$ to be the top-right angle of the intersection. $P$ is ordered so that $\angle_i < \angle_{i+1}$ for all $i$.

With these assumptions, $C$ defines the convex hull of $P$ iff the following conditions hold:

1. $C \subseteq P$.
2. $p_0 \in C$ and for all $i \in (0, n)$, $p_i \in C$ or the angle defined by the points $(\text{prv}_i, p_i, \text{nxt}_i)$ bends inwards, where $\text{prv}_i$ and $\text{nxt}_i$ are the first points before and after $p_i$ in $P$ that are also in $C$. If no such $\text{nxt}_i$ exists, then $\text{nxt}_i = p_0$.

Condition 1 ensures that $C$ contains no points outside $P$. Since $P$ is sorted, Condition 2 guarantees that $C$ contains all the points of $P$ that lie on the convex hull of $P$.

$T_S$ nondeterministically chooses $C$ and then checks the above conditions. The size of $C_{T_S}$ is in $O(n^2)$. (In particular, for each $p_i$, $T_S$ needs to iterate through $P$ again to find $\text{prv}_i$ and $\text{nxt}_i$.)

We use Graham Search as the $T_I$ for this problem. For each of the $n$ points, $T_I$ needs two STORE operations and two dynamic LOAD operations.

$T_E$ is shown in Fig. 8. It nondeterministically chooses $k, C$, and the points $\text{nxt}_i$, then it iterates over the $p_i$ and checks all relevant conditions in constant time for each $i$. The refinement proof showing $T_I \leq T_S$ uses the fact that $T_I$ computes the points in $C$ in the order in which they appear in $P$. Moreover, the $\text{nxt}_i$ can be computed by $T_{IE}$ using a simple linear scan of the final $C$.

To see that $T_E$ yields smaller constraints than $T_I$, observe that only the array access of $C[\text{count}]$ on Line 15 is dynamic and incurs the cost of two LOADs (one for each coordinate of the point). Also, there are no STORE operations. (Recall that a $\text{havoc}$ command stands for augmented code in $T_{IE}$. Hence, it does not contribute to $C_{T_E}$.) So $T_E$ only performs two dynamic LOAD operations per iteration. The cost of a STORE depends on how deeply it is nested in conditionals whereas the cost of a LOAD does not [91, §3.1]. Specifically, each STORE in $T_I$ is four times more expensive than a LOAD in $T_E$. We therefore expect that the size of $C_{T_E}$ is about five times smaller than that of $C_{T_I}$.

If we consider the variant where the problem is not to enumerate $C$ but to compute its characteristic function on the indices of $P$ (that is, mark the points in $P$ that belong to $C$), then we can eliminate all dynamic LOAD operations from $T_E$ and achieve an asymptotic $\log(n)$ factor improvement over $T_I$.
5.4 Maximal Strong Components

Given a directed graph $G = (V, E)$ with nodes $V$ and edges $E \subseteq V \times V$, the problem is to partition $V$ into the maximal strongly connected components $C_0, \ldots, C_{k-1}$ of $G$. We represent the $C_i$ implicitly using an array $\text{rank}$ that maps each node $v \in V$ to the index of its maximally strongly connected component. That is, we define for all $i \in [0,k)$, $C_i = \{ v \in V \mid \text{rank}[v] = i \}$. Given this, the formal problem statement is to find $k$ and $\text{rank}$ such that the following three conditions hold:

1. For all $v \in V$, $0 \leq \text{rank}[v] < k$.
2. For all $i \in [0,k)$, there exists a cycle $c_i$ in $G$ that visits exactly the nodes in $C_i$.
3. For all $i \in [0,k)$ and all cycles $c$ in $G$, if $c$ visits some node in $C_i$ then $c$ visits only nodes in $C_i$.

$T_S$ encodes the above specification by nondeterministically choosing $k$, $\text{rank}[v]$ for each node $v \in V$, and the cycles $c_i$ for each component $i \in [0,k)$. Condition 3 quantifies over the set of all cycles in $G$, which is in general an infinite set. However, it can be shown that restricting the quantification to simple cycles in $G$ yields an equivalent condition. A simple cycle is a path where only the first and last node are equal and all other nodes are distinct. The condition that quantifies over simple cycles can be encoded using a nested loop that iterates over all partial permutations $p$ of nodes in $G$ and then checks if $p$ forms a simple cycle in $G$ and intersects with a $C_i$, then it is fully contained in $C_i$. As the number of partial permutations grows exponentially with $|V|$, so does $|C_S|$.

We use Dijkstra’s MSC algorithm [33, Chapter 25] as our $T_I$. The algorithm iterates over $E$ and $V$. In each iteration, it performs up to $13$ LOAD and $8$ STORE operations. These operations dominate the size of the generated constraints.

However, we can again construct a $T_E$ that improves over both $T_I$ and $T_S$. The key idea for $T_E$ comes from Dijkstra’s correctness argument for his algorithm. Dijkstra observed that a set of connected components $C_0, \ldots, C_{k-1}$ is maximal iff it can be ordered so that all edges leaving a $C_i$ target only nodes in components preceding $C_i$. Given Dijkstra’s observation, we can replace Condition 3 in $T_S$ with the following condition in $T_E$:

$3^*$. For all $(v,w) \in E$, $\text{rank}[w] \leq \text{rank}[v]$.

Replacing Condition 3 by $3^*$ yields a refinement of $T_S$.

Additionally, Condition 2 can be reformulated as a Condition $2^*$ that no longer relies on the construction of explicit cycles $c_i$ connecting the nodes in each component. We observe that the nodes in each $C_i$ can be arranged in a tree that implicitly witnesses the existence of an appropriate $c_i$ (which we use in the $T_E \leq T_S$ proof). The tree reflects the way $T_I$ traverses the nodes in $V$ and collapses candidate components whenever a node is revisited. These trees can be obtained from $T_I$ using an augmentation that does not increase $T_I$’s asymptotic complexity. We use this augmentation to establish Condition $2^*$ when proving $T_I \leq T_E$.

Further details, including how Condition $2^*$ is expressed, are described in Appendix B [48]. What is important is that the combined size of these trees is linear in $|V|$ and so is checking their correctness. As a result, for dense graphs ($|E| \approx |V|^2$), the cost to enforce Condition $2^*$ is insignificant. A detailed cost analysis yields an expected reduction in total constraint size for dense graphs by a factor of 17.5 for sufficiently large $|E|$. For shallow graphs ($|E| \approx |V|$), we still obtain a reduction by a factor of two. The principal savings come from the fact that conditions $3^*$ and $2^*$ can be checked by $T_E$ (in the sense of validated inside an assume) with many fewer LOAD and STORE operations versus $T_I$.

Dijkstra’s MSC algorithm is similar to Tarjan’s algorithm [85]. We note that earlier work [24] already proposed an efficient checker for certifying the output of Tarjan’s algorithm. Their approach shares with ours that it constructs trees from the graph to efficiently check whether the computed components are connected. However, the details of how these trees guarantee the existence of a cycle for each component differ from the trees used by our $T_E$. Moreover, their approach does not immediately yield an efficient encoding into constraints.

5.5 Minimum Spanning Tree

Given a connected graph $G = (V,E)$ where undirected edges have unique positive weights, the problem is to find $M$, the unique minimum weight connected spanning subgraph of $G$. $M$ is called the minimum spanning tree (MST) of $G$. A natural, yet crude, specification is: $M$ is a set of $|V| - 1$ edges that is connected and spanning, and all other sets of $|V| - 1$ edges are either not connected, not spanning, or heavier than $M$. The $T_S$ that would encode this specification is exponential in $|V|$ because it needs to consider all $\binom{|E|}{|V|-1}$ candidates for $M$.

We will use an alternate definition for MST that leads to a more efficient $T_S$. Specifically, an MST, $M$, is the unique set of all edges that are not the heaviest in any cycle [76]. There are exactly $|V| - 1$ edges with this property. Thus, for all edges $e \in E \setminus M$, $e$ is the heaviest in at least one cycle. Our $T_S$ encodes this specification by nondeterministically picking an alleged MST $\bar{M}$ and then for each $e \in E \setminus \bar{M}$ (there are $|E| - |V| + 1$ such edges), providing a cycle where $e$ is heaviest. Notice that there is no need to explicitly consider edges $e \in \bar{M}$: after eliminating all $|E| - |V| + 1$ edges that are heaviest in some cycle, the remaining $|V| - 1$ edges $(\bar{M})$ are the unique MST. Cycles are $O(|V|)$ edges in the worst case, and there are $O(|E|)$ edges outside of $M$, so the complexity of this $T_S$ is dominated by $O(|V| \cdot |E|)$ edge lookups.

We use Kruskal’s algorithm [54] as our $T_I$. It starts with $M$ empty, sorts edges by weight, and iteratively adds edges to $M$ if they don’t form a cycle. This algorithm uses a Disjoint Set data structure to keep track of components of $M$ and detect cycles. This data structure forms a partition of $V$ into equivalence classes where two vertices are in the same class if they are connected by edges that have already been considered by the algorithm. Thus, when considering whether an edge $e$ does or doesn’t form a cycle with previous edges, Kruskal’s algorithm need only check whether both endpoints of $e$ are in the same equivalence class; if so, $e$ is not added to $M$, and if not, $e$ is added and the equivalence classes are merged.

The specific operations supported by a Disjoint Set data structure are:

- **MAKE-SET(v)**: turn vertex $v$ into a singleton set.
• FIND-SET(v): return a unique identifier (root vertex) for the set containing v; also, re-parent all vertices on the path from v to the root to point directly to the root.
• UNION(u, v): take two different set identifiers (vertices u and v) and join the two sets together. Some bookkeeping happens to minimize the depth of the union, which keeps FIND-SET calls cheap.

MAKE-SET and UNION both use $O(1)$ memory operations. We use an implementation [86] of this data structure in which FIND-SET(v) has an average-case complexity of $O(\alpha(|V|))$ memory operations (where $\alpha$ is the inverse Ackermann function) and a worst-case complexity of $O(|V|)$ memory operations.

Given the amortized complexity of FIND-SET(v), there are two ways to compile $T_I$ to constraints. One option is to unroll all FIND-SET(v) operations to their worst case $O(\log |V|)$ bounds. An alternative is to collect all nested loops into a state machine (as described in Buffet [91, §4]). The former results in $O(|E| \cdot |V|)$ RAM operations ($\S2$) with a small constant. The latter has better asymptotics, only requiring $O(|E| \cdot \alpha(|V|))$ RAM operations, but the overhead of the state machine introduces a large constant.

Our $T_E$ achieves both good asymptotics and a small constant. It builds on the idea behind widgets—checking FIND-SET rather than actually executing its logic—and introduces other techniques. The techniques are more fully described in Appendix C [48]. At a high level, our $T_E$ nondeterministically receives the MST $M$ and the history $H$ of the Disjoint Set operations; its constraints check the validity of $M$ and $H$ with respect to the input, the algorithm, and the data structure specification. This approach can be understood as directly encoding a special-purpose memory, namely the Disjoint Set data structure, as opposed to implementing that structure on a general-purpose RAM ($\S2$).

$T_E$ represents the history of $H$ as a table of tuples, where each tuple contains: the operation being performed (FIND-SET, UNION, and UPDATE, which is a new operation that abstracts steps of the implementation of FIND-SET, described further below), a vertex, its old parent, its new parent, and the weight of the edge being examined by this operation.

To check $H$ and $M$, $T_E$ needs to:
1. Check that $M$ is a $(|V| - 1)$-sized subset of $E$;
2. Check $H$ is consistent by verifying consistency between the old and new parent in consecutive operations on the same vertex;
3. Check that the data structure is consistent by ensuring MAKE-SET, FIND-SET, and UNION behave correctly and preserve the invariants of the Disjoint Set;
4. Check that for each edge $e$ not in $M$, $H$ reports that the endpoints of $e$ are in the same set; and
5. Check that for all edges in $M$, $H$ reports that the endpoints of each edge are in different sets and that the history merges those sets.

As an example, we elaborate on how to check that all FIND-SET operations are consistent (one component of the third check). Recall from earlier that a FIND-SET involves a sequence of re-parent operations. $T_E$ encodes that sequence using the aforementioned UPDATE. We now define UPDATE by way of an example. Consider a tuple with $(\text{UPDATE}, u, v, w, 23)$. The meaning of this tuple ap-
End-to-end system. To answer the first question, we implement our framework (§4) in a system also called Distiller. The system takes $T_5$, $T_E$, and $T_I$ as input. The system partially automates the refinement proofs and implements the new probabilistic proof pipeline proposed in Section 4.2. The input transition systems are expressed in a simple imperative programming language. Distiller’s input format enables the user to augment these transition systems with ghost code to be used in the refinement proofs, for Correctness and for Coupling.

To check Correctness, the system generates skeletons of the refinement proofs $T_I \leq T_E$ and $T_E \leq T_5$ from its input. The proof skeletons are expressed in the Viper intermediate verification language [69]. The user can augment these proof skeletons with proof annotations (e.g., loop invariants) and then check them using the Viper verification tool. For the proof of $T_I \leq T_E$, the system compiles the transition system $T_{IE}$ from the previous step and extracts the program $T_{IE}$, which it translates to a standard C program. The two generated programs are then fed into Pequin. Pequin in turn compiles $T_E$ to constraints $C_{IE}$, runs $T_{IE}$, and feeds the values into $C_{TE}$.

One of the constructs that Pequin supports is assertions. Each assertion translates to R1CS constraints checking that the assertion holds. Distiller uses this construct to compile the `assert` statements in $T_E$. Another Pequin construct is `exo_compute`, a hook allowing the prover to execute a program that produces values for arbitrary nondeterministic inputs to the generated constraints. This feature enables the prover to run $T_{IE}$ and supply the auxiliary inputs to $C_{IE}$ when solving the constraints.

To enable Coupling, Distiller takes $T_E$ from its input and translates it to the language accepted by the Pequin toolchain [75], which is a subset of C, extended with domain-specific constructs. Distiller also takes $T_{IE}$ from the previous step and extracts the program $T_{IE}$, which it translates to a standard C program. The two generated programs are then fed into Pequin. Pequin in turn compiles $T_E$ to constraints $C_{IE}$, runs $T_{IE}$, and feeds the values into $C_{TE}$.

To answer the first question, we implement our framework (§4) in a system also called Distiller. The system takes $T_5$, $T_E$, and $T_I$ as input. The system partially automates the refinement proofs and implements the new probabilistic proof pipeline proposed in Section 4.2. The input transition systems are expressed in a simple imperative programming language. Distiller’s input format enables the user to augment these transition systems with ghost code to be used in the refinement proofs, for Correctness and for Coupling.

To check Correctness, the system generates skeletons of the refinement proofs $T_I \leq T_E$ and $T_E \leq T_5$ from its input. The proof skeletons are expressed in the Viper intermediate verification language [69]. The user can augment these proof skeletons with proof annotations (e.g., loop invariants) and then check them using the Viper verification tool. For the proof of $T_I \leq T_E$, the system compiles the transition system $T_{IE}$ from the previous step and extracts the program $T_{IE}$, which it translates to a standard C program. The two generated programs are then fed into Pequin. Pequin in turn compiles $T_E$ to constraints $C_{IE}$, runs $T_{IE}$, and feeds the values into $C_{TE}$.

One of the constructs that Pequin supports is assertions. Each assertion translates to R1CS constraints checking that the assertion holds. Distiller uses this construct to compile the `assert` statements in $T_E$. Another Pequin construct is `exo_compute`, a hook allowing the prover to execute a program that produces values for arbitrary nondeterministic inputs to the generated constraints. This feature enables the prover to run $T_{IE}$ and supply the auxiliary inputs to $C_{IE}$ when solving the constraints.

To enable Coupling, Distiller takes $T_E$ from its input and translates it to the language accepted by the Pequin toolchain [75], which is a subset of C, extended with domain-specific constructs. Distiller also takes $T_{IE}$ from the previous step and extracts the program $T_{IE}$, which it translates to a standard C program. The two generated programs are then fed into Pequin. Pequin in turn compiles $T_E$ to constraints $C_{IE}$, runs $T_{IE}$, and feeds the values into $C_{TE}$.

One of the constructs that Pequin supports is assertions. Each assertion translates to R1CS constraints checking that the assertion holds. Distiller uses this construct to compile the `assert` statements in $T_E$. Another Pequin construct is `exo_compute`, a hook allowing the prover to execute a program that produces values for arbitrary nondeterministic inputs to the generated constraints. This feature enables the prover to run $T_{IE}$ and supply the auxiliary inputs to $C_{IE}$ when solving the constraints.

We perform an end-to-end evaluation of the resulting probabilistic proof pipeline composed of Distiller and Pequin for a select subset of our benchmarks. As a basic test of End-to-end Completeness, we apply the pipeline to the encoded benchmarks and successfully run it on a range of inputs. We note that the
overhead of executing $T_{IE}$ versus $T_I$ in the solving step is negligible compared to the rest of the pipeline (recall that Step 3 contributes negligibly to costs in the first place; §2). As a basic test of End-to-end Soundness, we also run Distiller with buggy versions of the $T_{IE}$. In these cases, the back-end correctly rejects the computation.

**Improved Reliability.** To answer Question (2) we check the $T_I \leq T_E$ and $T_E \leq T_S$ proofs for 10 of our 11 benchmark problems (§5) using Viper. We omit the MST benchmark in this experiment because, here, $T_S$ also encompasses the specification of a refined RAM, making the proof mechanization more elaborate.

Viper verifies all proofs. However, for two of the benchmarks we discovered bugs in the initial version of $T_E$. These bugs would have compromised End-to-end Soundness (§2). One bug was a missing array bounds check in $T_E$ of the merge computation (§3). The other one was a subtle omission of a check in $T_E$ for the Sum of Powers problem [33, Chapter 19]. We discovered these bugs when trying to annotate the respective $T_E$ to prove $T_E \leq T_S$.

**Constraint size reduction.** Recall that our primary performance metric is $|C|$ (§2). Our final experiment assesses Distiller against this metric. For all of our benchmarks, we generate $T_I$, $T_E$, and $T_S$ as input programs for Pequin to be compiled to constraints. Then, with the exception of MST, we run Pequin’s front-end on all three programs for a range of values for the loop unrolling bound that determines the maximal input size for each benchmark problem.

As MST relies on a refined RAM construct that is not available in Pequin, we calculate the size of the constraints generated by all RAM operations by hand and run Pequin on the rest of the program. We then combine the result of the two parts to obtain the final constraint size. We enforce a timeout threshold of 240s per run, with the exception of MSC and MST, where a 2000s threshold is chosen to enable computations on larger problem sizes. The maximal MSC instance size for which the translation of $T_E$ does not time out is $n = 20$, $m = 400$. This is still too small to observe the $17.5 \times$ theoretical improvement that we predict for dense graphs. Conversely, for the MST problem $T_I$ has a large constant overhead that causes the improvement achieved with $T_E$ to be $3 \times$ larger on small instances than the predicted $52.5 \times$ improvement for large problem instances. Finally, for binary search (BinS) we observe that the cost of storing the input array $A$ into RAM, which is linear in the size of the array, dwarfs the $\log(n)$ improvement achieved for a single invocation of the binary search (§5.2).

Figure 9 shows the results for the benchmarks where our theoretical analysis yields an improvement of $T_E$ over $T_I$ that converges to a constant factor with increasing problem instance size (Fig. 5). The results closely match our analysis. We note that for the MSC problem (§5.4), the relative improvement between $T_E$ and $T_I$ increases with the problem instance size. The maximal MSC instance size for which the translation of $T_I$ does not time out is $n = 20$, $m = 400$. This is still too small to observe the $17.5 \times$ theoretical improvement that we predict for dense graphs. Conversely, for the MST problem $T_I$ has a large constant overhead that causes the improvement achieved with $T_E$ to be $3 \times$ larger on small instances than the predicted $52.5 \times$ improvement for large problem instances. Finally, for binary search (BinS) we observe that the cost of storing the input array $A$ into RAM, which is linear in the size of the array, dwarfs the $\log(n)$ improvement achieved for a single invocation of the binary search (§5.2).

Figure 10 shows the results obtained for the three problems where our theoretical analysis predicts that $T_E$ performs asymptotically better than $T_I$ with increasing problem instance size. The experiment again confirms our predictions. In particular, for the merge problem discussed in §3, Figure 10a shows that $|C_{T_E}| / |C_{T_I}|$ is approximately hyperbolic, which we expect because the predicted improvement for each point is $L \times$, where $L$ is the number of merged arrays. Also, if we discount the RAM initialization cost for binary search, then we see the expected $\log(n)$ factor improvement (Fig. 10b).

## 7 Other related work

**Probabilistic proofs.** Section 2 gave an overview of probabilistic proof implementations, covering back-ends and front-ends; see also [87, 90, 93]. Unlike Distiller, none of the front-ends achieves all three requirements stated in the Introduction; in fact, none creates a framework for proving the correctness of widgets.

Distiller combines formal methods and probabilistic proofs. Very few works live at this intersection. Some notable exceptions are as follows. CirC [71] is a toolkit for building compilers to a family of constraint formalisms, including R1CS and SMT instances. Its architecture takes advantage of the rich SMT toolbox, allowing users to build powerful analyses and optimizations. The two works are complementary: one could compile a Distiller-verified widget in CirC, to get further reductions.

The Orbis Specification Language (OSL) [88] has a similar ideology to ours: replace a computation with its formal specification, and compile the latter to constraints, in the hope of gaining more concise specifications. However, as our examples (§5) make clear, the cost of a naive specification is often exorbitant. So one has to identify an “in-between” specification, and (a) relate it to the abstract specification, and (b) derive an implementation that knows how to satisfy the in-between specification or the original. Neither of these problems is addressed by OSL. The authors mention that they want to synthesize implementations from specifications. Though, for the rich specification language we consider (general transition systems), whether a specification even has an implementation is undecidable. Thus, to instantiate the ideology that OSL and we share, one needs human input (to write down $T_E$ and relate it to the specification and the implementation).

In an under-appreciated work, Fournet et al. [38] develop a compiler, based on CompCert [60], that formally connects the semantics of a higher-level program to the constraint formalism (specifically R1CS constraints). This work is complementary to Distiller—it provides Translation Fidelity (§2).

Leo [30] also has the goal of formally verified translations to constraints. Leo develops a compiler and uses the ACL2 [50] theorem prover to validate each stage of translation. However, this falls short of a verified compiler, as in Fournet et al. Moreover, the authors of Leo want to validate hand-crafted gadgets. It is not clear how to do this, since ACL2 cannot easily “reverse” R1CS instances to lift them to higher-level semantics. As a consequence, crucial pieces of verification are works in progress [30, §6.4]. By contrast, Distiller incorporates widgets soundly and completely, by treating them at the source code level and using refinement.

Another orthogonal work that combines formal methods and probabilistic proofs is zero knowledge abstract interpretation [36]. Here, the problem is to devise a scheme that enables a prover to convince a verifier of the result of a static program analysis run without revealing the analyzed program.
Refinement. The idea of developing a program from a specification in a step-wise refinement process goes back to early work by Dijkstra [32, 33] and Wirth [97]. The formal concept of refinement relations and mappings to relate the observable behaviors of transition systems was first explored in the 1980s [56, 57, 63]. It is a cornerstone of modern Formal Methods; applications include reasoning about concurrent and distributed systems, establishing program equivalence, and verifying security properties.

Abadi and Lamport [1] showed that refinement mappings yield a complete proof technique for establishing refinement. Though, in general, the technique requires the transition systems to be augmented with history variables (recording information about past states) and prophecy variables (predicting information about future states). Other related proof techniques for establishing refinement, for instance, based on (weak) simulation relations [66, 72, 89] are less suited for our purposes as they do not immediately provide a blueprint for computing satisfying assignments.

The notion of refinement considered in Distiller takes a monolithic view of transition systems, which makes it difficult to reason compositionally about subroutines. Contextual refinement [37] relates the observable behavior of subroutines subject to all possible client programs that may use them, thereby enabling compositional reasoning. For the relatively simple programming models supported by most existing probabilistic proof front-ends (no concurrency, object-oriented features, or higher-order functions), considering contextual refinement instead of global refinement does not add substantial complexity to the verification effort.

Distiller uses mechanized proofs (§6). Specifically, it uses a lightweight encoding of refinement proofs in the language of the deductive program verifier Viper [69]. The proofs are partially automated using SMT solvers. However, this is a choice. Nothing in our approach precludes or necessitates particular approaches to mechanization. In particular, there is a large body of work on refinement calculi that mechanize the correct step-wise refinement of programs and system models [2, 10, 65, 67, 68]. More recently, the many applications of proofs concerning products and couplings of two or more programs have fueled the development of relational program logics that provide frameworks for proof mechanization [11–13, 21, 39, 84, 99]. Several of these formal reasoning systems have been implemented in tools, including for instance TLA+ [58], Rodin [3], EasyCrypt [14], and ReLoC [39].

8 Discussion and conclusion

Distiller improves a key metric in implementations of probabilistic proofs, namely the number of arithmetic constraints required to encode the validity of the execution of a computation. The improvements typically range from small integer factors to orders of magnitude, depending on the computation. Distiller also introduces, for the first time, a framework for widgets that are correct by construction. This framework radically expands the space of potential widgets, thereby allowing probabilistic proofs to do much more, by paying much less.

The primary remaining verification gap is that we do not verify our tools, including the translator to the two targets, Pequin and Viper itself. This is not a fundamental limitation. In fact, we are encouraged by certified compiler work in this research area [38] to guarantee Translation Fidelity (§2). The TCB can be further reduced by using a verification toolchain with a small trusted core [6] (at the expense of reduced proof automation), or by deploying validation techniques that produce certificates for automatically generated proofs [34, 74].

Another limitation is that widgets are constructed manually. Identifying a \( T_E \) that slashes constraint size relative to \( T_S \) and \( T_E \), and then proving its correctness can take significant time and effort. A promising direction for future work is to adapt techniques from program synthesis [4] and superoptimizing compilers [49, 83] to automate these steps.

The code for Distiller is available at: https://github.com/PepperSieve/vprexocompiler
